(Fermilab Lattice and MILC Collaborations)

(Received 19 July 2014; published 30 October 2014)
We compute the leptonic decay constants $f_{D^+}$, $f_{D_s}$, and $f_K$ and the quark-mass ratios $m_c/m_s$ and $m_s/m_l$ in unquenched lattice QCD using the experimentally determined value of $f_{K^*}$ for normalization. We use the MILC highly improved staggered quark ensembles with four dynamical quark flavors—up, down, strange, and charm—and with both physical and unphysical values of the light sea-quark masses. The use of physical pions removes the need for a chiral extrapolation, thereby eliminating a significant source of uncertainty in previous calculations. Four different lattice spacings ranging from $a \approx 0.06$ to 0.15 fm are included in the analysis to control the extrapolation to the continuum limit. Our primary results are $f_{D^+} = 212.6(0.4)(^{+26}_{-18})$ MeV, $f_{D_s} = 249.0(0.3)(^{+3}_{-1})$ MeV, and $f_{D^*/f_{D^*}} = 1.1712(10)(^{+26}_{-38})$, where the errors are statistical and total systematic, respectively. The errors on our results for the charm decay constants and their ratio are approximately 2–4 times smaller than those of the most precise previous lattice calculations. We also obtain $f_{K^*/f_{K^*}} = 1.1956(10)(^{+26}_{-18})$, updating our previous result, and determine the quark-mass ratios $m_c/m_l = 27.35(5)(^{+10}_{-9})$ and $m_c/m_s = 11.747(19)(^{+50}_{-43})$. When combined with experimental measurements of the decay rates, our results lead to precise determinations of the Cabibbo-Kobayashi-Maskawa matrix elements $|V_{us}| = 0.22487(51)(^{+29}_{-20})(5), |V_{cd}| = 0.217(1)(5)(1)$ and $|V_{cs}| = 1.010(5)(^{+18}_{-6})$, where the errors are from this calculation of the decay constants, the uncertainty in the experimental decay rates, structure-dependent electromagnetic corrections, and, in the case of $|V_{us}|$, the uncertainty in $|V_{ud}|$, respectively.

I. INTRODUCTION AND MOTIVATION

The leptonic decays of pseudoscalar mesons enable precise determinations of Cabibbo-Kobayashi-Maskawa (CKM) quark-mixing matrix elements within the Standard Model. In particular, experimental rates for the decays $D^+ \to \mu^+\nu$, $D_s \to \mu^+\nu$ and $D \to \tau^+\nu$, when combined with lattice calculations of the charm-meson decay constants $f_{D^+}$ and $f_{D_s}$, allow one to obtain $|V_{cd}|$ and $|V_{cs}|$. Indeed, this approach results in the most precise current determination of $|V_{cd}|$. Similarly, the light-meson decay-constant ratio $f_{K^*}/f_{K^*}$ can be used to extract $|V_{us}|/|V_{ud}|$ from the experimental ratio of kaon and pion leptonic decay widths [1,2]. Here we calculate the charm decay constants for the first time using physical values for the light sea-quark mass. We obtain $f_{D^+}$ and $f_{D_s}$ to about 0.5% precision and their ratio $f_{D_s}/f_{D^+}$ to about 0.3% precision; we also update our earlier calculation of $f_{K^*}/f_{K^*}$ [3] to almost 0.2% precision. This is the most precise lattice calculation of the charm decay constants to date, and improves upon previous results by a factor of 2–4. We also compute the quark-mass ratios $m_c/m_s$ and $m_s/m_l$, which are fundamental parameters of the Standard Model.

We use the lattice ensembles generated by the MILC Collaboration with four flavors ($n_f = 2 + 1 + 1$) of dynamical quarks using the highly improved staggered quark (HISQ) action, and a one-loop tadpole improved Symanzik improved gauge action [4–7]. The generation algorithm uses the fourth-root procedure to remove the unwanted taste degrees of freedom [8–20]. Our data set includes ensembles with four values of the lattice spacing ranging from approximately 0.15 to 0.06 fm, enabling good control over the continuum extrapolation. The data set includes both ensembles with the light (up-down), strange, and charm sea masses close to their physical values (“physical-mass ensembles”) and ensembles where either the light sea mass is heavier than in nature, or the strange sea mass is lighter than in nature, or both.

The physical-mass ensembles enable us to perform first a straightforward analysis that does not require chiral fits. This analysis, which we refer to as the “physical-mass analysis” below, gives our results for $f_{K^*}/f_{K^*}$, as well as ratios of physical quark masses. The quark-mass ratios are then used as input to a more sophisticated analysis of the charm decay constants that includes the ensembles with unphysical sea-quark masses. In this second analysis, referred to as the “chiral analysis,” we analyze our complete data set within the framework of staggered chiral perturbation theory ($S\chi PT$) for all-staggered heavy-light mesons [21–23]. The inclusion of the unphysical-mass ensembles gives us tighter control on discretization effects because $S\chi PT$ connects the quark-mass and lattice-spacing dependence of the data, reducing the statistical errors on the decay constants significantly, and allowing us to make more refined adjustments for mistuning of masses. We therefore take our final central values for $f_{D^+}, f_{D_s}$, and $f_{D_s}/f_{D^+}$ from the chiral analysis. The physical-mass analysis provides a cross-check of the chiral analysis and is used in our final estimate of systematic uncertainties.

An earlier result for $f_{K^*}/f_{K^*}$ was presented in Ref. [3]. Here we update this analysis with slightly more statistics and improved estimates for the systematic errors. Preliminary results for the charm decay constants and quark masses were presented in Ref. [24].

This paper is organized as follows. Section II gives details about the lattice ensembles used in our calculation and the method for extracting the decay constants from two-point correlation functions. As discussed in Sec. III,
CHARMED AND LIGHT PSEUDOSCALAR MESON DECAY ... PHYSICAL REVIEW D 90, 074509 (2014)

the first stage in our analysis is to fit the two-point correlators to determine the meson masses and decay amplitudes for each pair of valence-quark masses. Section IV presents the main body of our analysis, which proceeds in two stages. In the first stage, described in Sec. IVA, we use the physical-mass ensembles to compute correlators to determine the meson masses and decay amplitudes at the resulting tuned valence masses. Next, in Sec. IVA 2, we adjust the quark-mass ratios and decay amplitudes to account for the slight sea-quark mass mistuning and extrapolate these results to the continuum. In the last part of the physical-mass analysis, Sec. IVA 3, we consider systematic errors from finite-volume and electromagnetic effects. In the second analysis stage described in Sec. IV B, we use heavy-light staggered quark-mass ensembles to obtain the charm-meson decay constants. In the first part of this calculation, the first stage in our analysis is to fit the two-point correlators to determine the meson masses and decay amplitudes. We then discuss the required mass-independent scale setting in Sec. IV B 1. We then discuss the mass-independent scale setting in Sec. IV B 2, where we take care to correct for effects on the scale and quark-mass estimates of mistunings of the sea-quark masses. We present the chiral-continuum fits in Sec. IV B 3 and discuss the systematic errors from the continuum extrapolation, as well as from other sources, in Sec. IV B 4. We present our final results for the decay constants and quark-mass ratios with error budgets in Sec. V, in which we also compare our results to other unquenched lattice calculations. Finally, we discuss the impact of our results on CKM phenomenology in Sec. VI. The Appendix gives details about the inclusion of non-leading heavy-quark effects in our chiral formulas.

II. LATTICE SIMULATION PARAMETERS AND METHODS

Table I summarizes the lattice ensembles used in this calculation. Discussion of the parameters relevant to the lattice generation, such as integration step sizes and acceptance rates, choice of the rational hybrid Monte Carlo (RHMC) or rational hybrid molecular dynamics (RHMD) algorithm, and autocorrelations of various quantities can be found in Ref. [7]. In particular, we find that the effects of using the RHMD algorithm rather than the RHMC algorithm in some of our ensembles are negligible. The dependence of error estimates for the decay constants in this work on the jackknife block size is consistent with the more general

</table>
results on autocorrelations in Ref. [7]. Reference [7] also shows the molecular dynamics time evolution of the topological charge for many of these ensembles and histograms of the topological charge. We have since also verified that on the \( a \approx 0.06 \) fm physical quark mass ensemble the autocorrelation time for the topological charge is much shorter than the topological charge autocorrelation time on the \( a \approx 0.06 \) fm, \( m'_f = m_f / 5 \) ensemble shown in Fig. 2 of Ref. [7]. The dependence on the light-quark mass can be understood by thinking of the decorrelation process as a random walk in the topological charge.

Our extraction of the pseudoscalar decay constants with staggered quarks follows that used for asqtad quarks [2,25] and for \( f_{K^0} \) with the HISQ action [3,26]. The decay constant \( f_{PS} \) is given by the matrix element of \( \bar{\psi} \psi \) between the vacuum and the pseudoscalar meson. For staggered fermions, using the pion taste corresponding to the axial symmetry broken only by quark masses, this becomes the operator

\[
O_p(\vec{x}, t) = \bar{\chi}^a(\vec{x}, t)(-1)^{s+y+z+t}\chi^a(\vec{x}, t),
\]

where \( a \) is a color index. The desired matrix element can be obtained from the amplitude of a correlator using this operator at the source and sink:

\[
P_{PP}(t) = \frac{1}{V_s} \sum_{\vec{y}} \langle O_p(\vec{y}, 0) O_p(\vec{0}, t) \rangle = C_{PP} e^{-Mt} + \text{excited state contributions},
\]

where \( V_s \) is the spatial volume, \( M \) is the pseudoscalar meson mass and the sum over \( \vec{y} \) isolates the zero spatial momentum states. Then the decay constant is given by [27,28]

\[
f_{PS} = (m_A + m_B) \sqrt{\frac{V_s}{4}} \sqrt{\frac{C_{PP}}{M^3}},
\]

where \( m_A \) and \( m_B \) are valence quark masses and \( M \) is the pseudoscalar meson mass.

In our computations, we use a “random-wall” source for the quark propagators, where a randomly oriented unit vector in color space is placed on each spatial site at the source time. Then quark and antiquark propagators originating on different lattice sites are zero when averaged over the sources. We use three such source vectors for each source time slice.

We also compute pion correlators using a “Coulomb-wall” source, where the gauge field is fixed to the lattice Coulomb gauge, and then a uniform color vector source is used at each spatial site. In practice these vectors are the “red,” “green,” and “blue” color axes. The Coulomb-wall source correlators are somewhat less contaminated by excited states than the random-wall source correlators, so by simultaneously fitting the correlators with common masses we are able to determine the masses better, and hence get a better determined amplitude for the random-wall source correlator.

Four source time slices are used on each lattice, with the exception of the 0.06 fm physical quark-mass ensemble where, because these lattices are longer in the Euclidean time direction, six source time slices are used. The location of the source time slices on successive lattices is advanced by an amount close to one-half of the spacing between sources, but incommensurate with the lattice time size, so that the source location cycles among all possible values.

In each lattice ensemble, two-point correlators are computed for a range of valence-quark masses. The complete set of valence-quark masses is given in Table II. The lightest

</table>
valence mass used is one-tenth the strange-quark mass for the coarser ensembles with heavier sea-quark masses, 1/20 the strange-quark mass for the $a \approx 0.06$ fm ensembles with heavier than physical sea-quark mass, and the physical light-quark mass for the ensembles with physical sea-quark mass. The valence masses chosen then cover the range from this lightest mass up to the estimated strange-quark mass. We then choose additional masses at the estimated charm-quark mass (the same as the charm-quark mass in the sea), as well as nine-tenths of that value, so that we can make adjustments for mistuning of the charm-quark mass. For these last two quarks, the coefficient of the three-link term in the fermion action (the “Naik term”) is adjusted to improve the quark’s dispersion relation [29]. Specifically, the expansion resulting from combining Eqs. (24) and (26) of Ref. [29] is used; the improvement has been checked in HISQ simulations [6,29].

III. TWO-POINT CORRELATOR FITS

To find the pseudoscalar masses and decay amplitudes, the random-wall and Coulomb-wall correlators are fitted to common masses but independent amplitudes. With staggered quarks the Goldstone-taste pseudoscalar correlators with unequal quark masses contain contributions from opposite-parity states, which show up as exponentials with unequal quark masses contain contributions from common masses but independent amplitudes. With staggered random-wall and Coulomb-wall correlators are fitted to simulations[6,29].

To make the fits converge reliably, it is necessary to loosely constrain the masses of the opposite-parity and excited states by Gaussian priors. The central value of the gap between the ground state and opposite parity states is taken to be 400 MeV, motivated by the 450 MeV gap between the $D$ mass and the $0^+$ light-charm mass, and the 350 MeV gap between the $D_s$ mass and a poorly established $0^-$ strange-charm meson [30]. The central value for the gap between the ground state and excited state masses is taken to be 700 MeV, motivated by the 660 MeV gap between the $\eta_c$ and the corresponding $2S$ state. In most cases the widths of the priors for the opposite-parity and excited state gaps are taken to be 200 and 140 MeV, respectively, although in some cases these need to be adjusted to get all of the jackknife fits to converge.

Another factor that makes the light-charm correlators more difficult to fit is the faster growth of the statistical error. The time dependence of the variance of a correlator is expected to depend on time as $e^{-E_2 t}$, where $E_2$ is the energy of the lowest lying state created by $OO^\dagger$, where $O$ is the source operator for the correlator itself, with the proviso that quark and antiquark lines all go from source to sink, rather than coming back to the source [31]. For the pion correlator, the state created by $OO^\dagger$ is just the two-pion state, leading to the expectation that the fractional statistical error on the pion correlator is roughly independent of distance. However, for the light-charm correlator, the quarks and antiquarks created by $OO^\dagger$ can pair up to form an $\eta_c$ and a pion. Then, the reduction of the pion’s mass from chiral symmetry makes this state much lighter than $2M_D$, so the fractional error of the propagator grows rapidly with distance. This makes it essential to use smaller minimum distances in the fit range for the light-charm correlators, which of course makes the problem of excited states discussed in the previous paragraph even more serious.

Table III shows our expectations for the states controlling the growth of statistical errors for the various pseudoscalar correlators. Figure 1 shows the fractional errors for the

Table III. States expected to control the statistical errors on the correlators, for the pseudoscalars with physical valence-quark masses. The second column shows the state expected to control the growth of the statistical error on the correlator, the third column the mass gap between half the mass of the error state and the particle mass, and the fourth column the length scale for the growth of the fractional statistical error. Here $\bar{s}s$ is the unphysical flavor nonsinglet state, with mass 680 MeV.
random-wall correlators for the 0.09 fm physical quark-mass ensemble, with comparison to the slopes expected from the states in Table III, which give a good approximation to the observed growth of the errors with the exception of the charm-charm correlator.

Figures 2 and 3 show the masses in the $2 + 1$ state fits for the light-charm correlators in the $a = 0.09$ fm physical quark-mass ensemble as a function of the minimum distance included in the fit, where the light-quark mass is the physical $(m_u + m_d)/2$ (Fig. 2) and $m_s$ (Fig. 3). Fit ranges are chosen from graphs like this for all the ensembles, and analogous graphs for the light-light and charm-charm correlators. We show this ensemble because it, together with the $a = 0.06$ fm physical-mass ensemble, is the most important to the final results. In these graphs the error bars on the right show the central values and widths of the priors used for the opposite-parity and excited masses. At short distances, these masses are more accurately determined by the data, while at larger $D_{min}$ the input prior controls the mass. The linear sizes of the symbols in these figures are proportional to the $p$ value of the fit, with the size of the symbols in the legend corresponding to 50%. In the two-point correlator fits used to choose the fit types and ranges, as in Figs. 2 and 3, autocorrelations among the lattices are minimized by first blocking the data in blocks of four lattices, or $10^{-24}$ molecular dynamics time units. However, statistical errors on results in later sections are obtained from the jackknife procedures described in Secs. IVA and IV B. In these analyses the two-point fits are repeated in each jackknife resampling. From these and similar graphs for other ensembles and different numbers of excited states, keeping the minimum distance in physical units reasonably constant, the minimum distances and fit forms in Table IV are chosen. The need for using a smaller minimum distance and including an excited state in the heavy-light fits is consistent with our expectations from Table III and Fig. 1. Because the statistical errors increase with distance from the source, the fits are much less

FIG. 1 (color online). Fractional errors for pseudoscalar correlators as a function of distance from the 0.09 fm physical quark-mass ensemble. The line segments show the slope expected from the states in Table III, which give a good approximation to the observed growth of the errors with the exception of the charm-charm correlator.

FIG. 2 (color online). Fits for the light-charm pseudoscalar correlator (mass $M$) in the ensemble with $a \approx 0.09$ fm and physical sea-quark masses. We plot the ground state, alternating state (opposite parity) and excited state masses as a function of minimum distance included in the fit. The size of the symbols is proportional to the $p$ value of the fit, with the size of the symbols in the legend corresponding to 0.5. The two bursts on the right show the priors and their errors for the alternating and excited masses. The vertical arrows at $D_{min} = 15$ indicate the fit that is chosen. Further discussion is in the text. Here the masses and distance are in units of the lattice spacing.

FIG. 3 (color online). Fits for the strange-charm correlator in the ensemble with $a \approx 0.09$ fm and physical sea-quark masses. The format and symbols are the same as in Fig. 2.
TABLE IV. Fit forms and minimum distance included for the two-point correlator fits. Here the fit form is the number of negative parity (i.e., pseudoscalar) states “plus” the number of positive parity states. When the valence quarks have equal masses, the opposite-parity states are not included. In this work the charm-charm fits are needed only for computing the mass of the \( \eta_c \) meson, used as a check on the quality of our charm physics.

Sensitive to the choice of maximum distance. In most cases the maximum distance is taken to be one less than the midpoint of the lattice. However, in the \( a \approx 0.09 \) and \( 0.06 \text{ fm} \) ensembles, the light-charm and charm-charm fits used a smaller maximum distance because having fewer points in the fit gave a better conditioned covariance matrix. These maximum distances are also included in Table IV.

IV. DETERMINATION OF DECAY CONSTANTS AND QUARK-MASS RATIOS

This section describes the details of the analyses that produce our results for light-light and heavy-light decay constants and the ratios of quark masses. We perform two versions of the analysis. The first, the “physical-mass analysis” described in Sec. IV A, is a straightforward procedure that essentially uses only the physical-quark mass ensembles. On these ensembles, a chiral extrapolation is not needed: only interpolations are required in order to find the physical-quark-mass point. The physical-mass analysis produces our results for quark-mass ratios and \( f_{K^+}/f_{\pi^+} \), as well as some additional intermediate quantities required for the chiral analysis of the \( D \) meson decay constants, which follows. The second analysis of charm decay constants, described in Sec. IV B, uses chiral perturbation theory to perform a combined fit to all of our physical-mass and unphysical-mass data, and to thereby significantly reduce the statistical uncertainties of the results. We take the more precise values of \( f_{D^+}, f_{D_s} \), and their ratio from the chiral analysis as our final results, and use those from the simpler physical-mass analysis only as a consistency check, and to aid in the estimation of systematic errors.

In the physical-mass analysis of Sec. IV A, we first determine the lattice spacing and quark masses separately for each ensemble, using, in essence, the five experimental values of \( f_{\pi^+}, M_{\pi^0}, M_{K^0}, M_{K^+} \) and \( M_D \), as explained in Sec. IV A 1. In order to adjust for mistuning of the sea-quark masses, we perform a parallel scale-setting and quark-mass determination on the unphysical-mass ensembles; there, however, an extrapolation in the valence-quark mass is generally required. We extrapolate the quark-mass ratios to the continuum, after small sea-quark mistuning adjustments, in Sec. IV A 2. We follow the same procedure on the physical-mass ensembles to also obtain values for decay constants. In particular, we update our result for \( f_{K^+}/f_{\pi^+} \) from Ref. [3]. Although the results for charm decay constants from the physical-mass analysis are not taken as our final values, they are used as additional inputs in the estimation of systematic errors from the continuum extrapolation. Finally, the physical-mass analysis allows us to make straightforward estimates of systematic errors coming from finite-volume and electromagnetic (EM) effects on the decay constants and quark-mass ratios, as described in Sec. IV A 3.

The values of the physical quark-mass ratios \( m_c/m_s, m_t/m_s \), and (to a lesser extent, in order to take into account isospin-violating effects) \( m_c/m_s \) obtained in Sec. IV A are used in the subsequent chiral analysis in Sec. IV B. Further, in the physical-mass analysis, we determine the useful quantity \( F_{p_{ks}} \) [7], which is the light-light pseudoscalar decay constant \( F \) evaluated at a fiducial point with both valence masses equal to \( m_{p_{ks}} \equiv 0.4 m_s \) and physical sea-quark masses. The meson mass at the same fiducial point, \( M_{p_{ks}} \), as well as the ratio \( R_{p_{ks}} \equiv F_{p_{ks}}/M_{p_{ks}} \), are similarly determined. The unphysical decay constant \( F_{p_{ks}} \) provides an extremely precise and convenient quantity to set the relative scale in the chiral analysis (see Sec. IV B 2), while we use \( R_{p_{ks}} \) to tune the strange sea-quark mass.

The chiral analysis of the decay constants of charm mesons is described in detail in Sec. IV B. With chiral perturbation theory, one can take advantage of all our data by including both the physical-mass and unphysical-mass ensembles in a unified procedure. In particular, the statistical error in \( \Phi_D \) is slightly more than a factor of 2 smaller with the chiral analysis than in the physical-mass analysis of Sec. IV A. In addition, the use of the relevant form of staggered chiral perturbation theory for this case, heavy-meson, rooted, all-staggered chiral perturbation theory (HM\textsubscript{rAS}\textsubscript{PT}) [23], allows us to relate the quark-mass and lattice-spacing dependence of the data, and thereby use the unphysical-mass ensembles to tighten the control of the continuum extrapolation. Our final central values for the charm decay constants given in the conclusions are taken from the chiral analysis. We increase some of the systematic uncertainties, however, to take into account differences with the results of the physical-mass analysis.
**A. Simple analysis from physical quark-mass ensembles**

Here we determine the quark-mass ratios and decay constants employing primarily the physical quark-mass ensembles. First, in Sec. IVA 1, we determine the lattice spacing, quark masses, and decay constants separately for each ensemble. Next, in Sec. IVA 2, we adjust the quark masses and decay constants for slight sea-quark mass mistuning, and extrapolate to the continuum. Finally, we estimate the systematic uncertainties in the quark-mass ratios and decay constants in Sec. IVA 3. We present results and error budgets for these quantities obtained from the physical mass analysis in Table VI.

**1. Valence-quark mass interpolation**

In this stage of the analysis we determine tuned quark masses and the lattice spacing (using \( f_{\pi^+} \) to fix the scale) for each ensemble, and then find the decay constants by interpolation or extrapolation in valence-quark mass to these corrected quark masses. There are a number of possible choices for the procedure used, and we include the differences among a few sets of choices in our systematic error estimate. It is important to remember that there is inherent ambiguity in defining a lattice spacing for ensembles with unphysical sea-quark masses, but all sensible choices should have the same limit at zero lattice spacing and physical sea-quark masses. For example, in the ensemble-by-ensemble fitting procedure described in this section, we take the value of \( f_{\pi^+} \) on each ensemble to be 130.41 MeV, independent of sea-quark masses, while for the chiral perturbation theory analysis we take the lattice spacing to be independent of the sea-quark masses.

Figure 4 illustrates some of the features of our procedure, and referring to it may help clarify the following description. Since the decay amplitude \( \mathcal{D} \) depends on valence-quark mass, and we wish to use \( f_{\pi^+} = 130.41 \) MeV to set the lattice scale, we must determine the lattice spacing and tuned light-quark mass simultaneously. To do so, we find the light valence-quark mass where the mass and amplitude of the pseudoscalar meson with degenerate valence quarks have the physical ratio of \( M_\pi^2/f_{\pi^+}^2 \). (Actually we adjust this ratio for finite size effects, using the pion mass and decay constant in a 5.5 fm box. This correction is discussed in Sec. IVA 3.) This light-quark mass is the average of the up- and down-quark masses, \( m_v = (m_u + m_d)/2 \). Here we use the mass of the \( \pi^0 \), since it is less affected by electromagnetic corrections than the \( \pi^+ \). Since the \( \pi^+ \) contains one up and one down quark, the error in \( f_{\pi^+} \) from using degenerate light valence quarks is negligible. This tuning is illustrated in the upper left panel of Fig. 4, which shows this ratio as a function of light valence mass for the 0.09 fm physical quark-mass ensemble, one of the two ensembles that are most important in our analysis. The octagons in this panel are the ratio at the valence-quark masses where we calculated correlators, with error bars that are too small to be visible. The horizontal red line is the desired value of this ratio, and the green vertical line shows the light-quark mass where the ratio has its desired value. With the tuned light-quark mass determined, we use the decay amplitude at this mass, \( f_{\pi^+} \), to fix the lattice spacing. In performing the interpolation or extrapolation of \( M_\pi^2/f_{\pi^+}^2 \) we use points with degenerate light valence-quark mass \( m_v \) and employ a continuum, partially quenched, SU(2) \( \chi PT \) form [22,32],

\[
\begin{align*}
M_\pi^2 &= \frac{B_2 m_v}{f_{\pi^+}^2} \left\{ 1 + \frac{1}{16 \pi^2 f_{\pi^+}^2} \left[ B(4m_v - 2m_l^0) \log(2Bm_v/\Lambda_\chi^2) + 4B(m_v + m_l^0) \log(B(m_v + m_l^0)/\Lambda_\chi^2) + Cm_v \right] \right\}, \\
f_{\pi^+} &= f \left\{ 1 - \frac{2B(m_v + m_l^0)}{16 \pi^2 f_{\pi^+}^2} \log(B(m_v + m_l^0)/\Lambda_\chi^2) + Cm_v + Dm_v^2 \right\},
\end{align*}
\]

where \( m_l^0 \) is the light sea-quark mass and \( \Lambda_\chi \) is the chiral scale. In applying Eq. (4), we fix the low-energy constants \( B \) and \( f \) in the coefficients of the logarithms to values determined from lowest order \( \chi PT \) using the smallest valence-quark mass. We then fix the coefficients of \( m_v \) and \( m_l^2 \) in \( M_\pi^2/f_{\pi^+}^2 \) using the smallest two valence-quark masses available, and we fix the analytic coefficients in \( f_{\pi^+} \) using the three smallest valence-quark masses. In the
CHARMED AND LIGHT PSEUDOSCALAR MESON DECAY ...

This mass. Using linear interpolations in $m_s$ of the $D_s$ meson mass at these two "charm" masses to the strange-quark mass found earlier, and a linear interpolation in $m_c$ between these, we find a tuned charm-quark mass.

Now that we have found the lattice spacing and tuned quark masses, we can find decay constants and masses of other mesons by interpolating or extrapolating to these quark masses. The bottom panel of Fig. 4 illustrates this process. The lower set of points in this graph are the decay constants at each light valence mass, interpolated using the two strange valence masses to the tuned strange-quark mass. Then $f_{K^-}$ is found by extrapolating these points to the tuned $m_u$, illustrated by the red octagon at the lower left. Similarly, the upper set of data points is the decay constant at each light-quark mass, linearly interpolated or extrapolated using the two charm valence masses to the tuned $m_c$. This graph is then interpolated or extrapolated to the tuned $m_d$ to find $f_{D_s}$, shown in the red octagon at the upper left, or to the tuned $m_s$ to find $f_{D_s}$, shown by the red octagon at the upper right.

As checks on our procedure, we also similarly interpolate or extrapolate in the meson masses to find $M_{f^{0}}, M_{D^{+}}$, and $M_{B_s}$.

2. Sea-quark mass adjustment and continuum extrapolation

In this stage we combine the results from the individual ensembles and fit to a function of the lattice spacing to find the continuum limit. We use the ensembles with unphysical sea-quark masses to make small adjustments for the fact that the sea-quark masses in the physical quark-mass ensembles were fixed after short tuning runs, and inevitably turned out to be slightly mistuned when the full runs are done. The amount of mistuning is shown in Table V, which gives the sea-quark masses and the tuned quark masses for the physical quark-mass ensembles.

Fitting to the lattice spacing dependence is straightforward, because the results from each ensemble are statistically independent. We have performed continuum extrapolations for the ratios of quark masses, $m_u/m_d$, $m_s/m_d$, and $m_c/m_s$, which come automatically from the fitting for each ensemble described in Sec. IVA 1. Figures 5–7 show the results for each ensemble, together with fits to the lattice spacing dependence. In these plots the

physical quark-mass ensembles, such as the one shown in Fig. 4, this is only a small correction to the quark mass. On the other hand, in most of the ensembles with $m_u/m_s = 0.1$ or 0.2, the lightest valence-quark mass is 0.05$m_d$ or 0.1$m_s$, and a significant extrapolation is made. However, these unphysical-mass ensembles are used only in the analysis of this section to correct the results of the physical-mass ensembles for small mistunings of the sea masses in the physical-mass ensembles.

We then fix the tuned strange-quark mass to the mass that gives the correct $2M_{K_{s}} - M_{K}$. This is illustrated in the upper right panel of Fig. 4. In all of our ensembles, we use valence "strange"-quark masses at the expected strange-quark mass and at 0.8 times this mass. The two data points shown in the figure have these strange masses and the lightest available light-quark valence mass. A linear interpolation or extrapolation is performed through these two points. Again, the horizontal red line shows the desired value of this mass difference, and the vertical green line the resulting value of $m_c$. In this stage of the tuning the kaon mass is corrected for finite-volume effects, electromagnetic effects and isospin breaking effects, where again we defer the details to the discussion of systematic errors in Sec. IVA 3.

Next we determine the up- and down-quark masses, and hence the up- and down-quark masses. We use the difference in $K^0$ and $K^+$ mass:

$$m_d - m_u = \frac{M_{K_{s}}^2 - M_{K}^2}{\partial M_{K}^2/\partial m_\ell}.$$  (5)

Here the kaon masses are adjusted for finite-volume and electromagnetic effects, and again we defer the details to Sec. IVA 3. We note that the electromagnetic corrections are a small effect on the strange quark-mass tuning but are absolutely crucial in the determination of $m_d - m_u$. To estimate the derivative $\partial M_{K}^2/\partial m_\ell$, we use the masses of kaons containing a valence quark near the strange-quark mass and a second valence quark that is one of the two lightest valence quarks we have.

Then the tuned charm-quark mass is determined from the experimental value of $M_{D_{s}}$. We use $M_{D_{s}}$ rather than $M_{D}$ because it has much smaller statistical errors. In all of our ensembles we have correlators with valence-quark masses at the expected charm-quark mass and at 0.9 times this mass.

### Table V. Tuned lattice spacings (using $f_{K^0}$ to set the scale) and quark masses for the physical quark-mass ensembles. The quark-mass entries show the light-, strange- and charm-quark masses in units of the lattice spacing. The column labeled $am'$ gives the run values of the sea-quark masses.

</table>
The abscissa is \( a_s^2 \alpha_S \), where \( \alpha_S \) is an effective coupling constant determined from taste violations in the pion masses. The relative value of \( \alpha_S \) at a given coupling \( \beta \), compared to its value at a fixed, fiducial coupling \( \beta_0 \), is given by

\[
\frac{\alpha_S(\beta)}{\alpha_S(\beta_0)} = \sqrt{\frac{(a_s^2 \Delta)_{\beta} a_s^2(\beta_0)}{(a_s^2 \Delta)_{\beta_0} a_s^2(\beta)}} \tag{6}
\]

where \( (a_s^2 \Delta)_{\beta} \) is the mean squared taste splitting at coupling \( \beta \), and \( a(\beta) \) is the lattice spacing given below.

In Table VIII, Equation (6) assumes that \( a_s^2 \Delta \) is proportional to \( a_s^2 a^2 \), its leading behavior. We use \( \beta_0 = 5.8 \) in these plots and scale \( \alpha_S \) to agree with the coupling \( \alpha_V \) at \( \beta_0 = 5.8 \), which in turn may be determined from the plaquette [33] as explained after Eq. (9) of Ref. [7].

In these figures the fit used to determine the central value is shown in black. This is a quadratic polynomial fit through the four physical quark-mass points. In this fit, small adjustments have been made to compensate for sea-quark mass mistuning. To make these adjustments, the derivative of each quantity with respect to sea-quark mass is found from a fit including both the physical quark-mass ensembles and the \( m_0 \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7. Other fits shown in these figures are used in estimating the systematic error resulting from our choice of fitting forms. The blue lines in each figure show the fit including the \( 0.1 m'_i \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7. Other fits shown in these figures are used in estimating the systematic error resulting from our choice of fitting forms. The blue lines in each figure show the fit including the \( 0.1 m'_i \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7. Other fits shown in these figures are used in estimating the systematic error resulting from our choice of fitting forms. The blue lines in each figure show the fit including the \( 0.1 m'_i \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7.

In Table VIII, Equation (6) assumes that \( a_s^2 \Delta \) is proportional to \( a_s^2 a^2 \), its leading behavior. We use \( \beta_0 = 5.8 \) in these plots and scale \( \alpha_S \) to agree with the coupling \( \alpha_V \) at \( \beta_0 = 5.8 \), which in turn may be determined from the plaquette [33] as explained after Eq. (9) of Ref. [7].

In these figures the fit used to determine the central value is shown in black. This is a quadratic polynomial fit through the four physical quark-mass points. In this fit, small adjustments have been made to compensate for sea-quark mass mistuning. To make these adjustments, the derivative of each quantity with respect to sea-quark mass is found from a fit including both the physical quark-mass ensembles and the \( 0.1 m'_i \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7. Other fits shown in these figures are used in estimating the systematic error resulting from our choice of fitting forms. The blue lines in each figure show the fit including the \( 0.1 m'_i \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7.

In Table VIII, Equation (6) assumes that \( a_s^2 \Delta \) is proportional to \( a_s^2 a^2 \), its leading behavior. We use \( \beta_0 = 5.8 \) in these plots and scale \( \alpha_S \) to agree with the coupling \( \alpha_V \) at \( \beta_0 = 5.8 \), which in turn may be determined from the plaquette [33] as explained after Eq. (9) of Ref. [7].

In these figures the fit used to determine the central value is shown in black. This is a quadratic polynomial fit through the four physical quark-mass points. In this fit, small adjustments have been made to compensate for sea-quark mass mistuning. To make these adjustments, the derivative of each quantity with respect to sea-quark mass is found from a fit including both the physical quark-mass ensembles and the \( 0.1 m'_i \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7. Other fits shown in these figures are used in estimating the systematic error resulting from our choice of fitting forms. The blue lines in each figure show the fit including the \( 0.1 m'_i \) ensembles, and this derivative is used to adjust each point in the fit. The resulting adjustments are too small to be visible in Figs. 5, 6, and 7.

In Table VIII, Equation (6) assumes that \( a_s^2 \Delta \) is proportional to \( a_s^2 a^2 \), its leading behavior. We use \( \beta_0 = 5.8 \) in these plots and scale \( \alpha_S \) to agree with the coupling \( \alpha_V \) at \( \beta_0 = 5.8 \), which in turn may be determined from the plaquette [33] as explained after Eq. (9) of Ref. [7].
The four extrapolations in Figs. 5, 6, and 7, together with quadratic fits to the physical mass points using \( a \alpha a^2 \) or \( a^2 \) as the abscissa, make a set of six continuum extrapolations for these and other quantities. The six versions are used to estimate the systematic errors of the quark-mass ratios and light-meson decay constants and to inform the systematic error analysis of Sec. IV B 4.

In Fig. 5 and, to a lesser extent in Figs. 6 and 7, the points at small lattice spacing with unphysical light sea-quark masses deviate strongly from the physical sea-quark mass points. This is mostly a partial quenching effect that shows up for valence-quark masses small compared to the light sea-quark mass. In particular, the squared pseudoscalar meson mass is increased by a partially quenched chiral log, which means that a smaller tuned light valence-quark mass is needed to give the desired \( M^2 / F^2 \). This has the direct effect of increasing \( m_s / m_l \), with smaller effects on all other quantities. This is mostly seen at the smallest lattice spacing because at larger lattice spacings taste violations smear out the chiral logs. Note that this partial quenching effect has negligible effect on our results for \( m_s / m_l \) and \( m_c / m_s \), which depend almost exclusively on the data from the physical-mass ensembles.

We perform similar continuum extrapolations for the ratios of decay constants \( F_{ps} / f_{X^+}, f_{K^+} / f_{X^+}, f_{D^+} / f_{X^+}, f_{D_s^+} / f_{X^+} \), and \( f_{D_s^+} / f_{D^+} \), and for \( M_{ps} \) and \( R_{ps} = F_{ps} / M_{ps} \). Figure 8 shows the individual ensemble values and the same set of continuum extrapolations for the ratio \( f_{K^+} / f_{X^+} \). As an example of a quantity involving a charm quark, Fig. 9 shows values and continuum extrapolations for the ratio \( f_{D_s^+} / f_{X^+} \). The extrapolated value for \( f_{K^+} / f_{X^+} \) is our result for this quantity. Figure 10 shows the continuum extrapolations for \( F_{ps} \) and \( R_{ps} \). The resulting continuum values for \( F_{ps} \) and \( R_{ps} \) are used in the later analysis in Sec. IV B. The values for the charm-meson decay constants provide consistency checks on the analysis in Sec. IV B, and the spread in continuum values among the different extrapolations is included in our estimates of the systematic uncertainty from the continuum extrapolation. Finally, as a check, we extrapolate the mass of the \( \eta_c \) meson. These continuum extrapolations and their statistical errors are shown in Table VI.

Statistical errors on these quark-mass ratios and decay constants are estimated with a jackknife method, where for each ensemble we perform the entire fitting procedure eliminating one configuration at a time. Autocorrelations are handled by estimating the final error from the variance of the jackknife resamples, after first blocking the jackknife results in blocks of 20 (eliminated) lattices, which corresponds to 50 molecular dynamics time units for the \( a \approx 0.15 \) fm physical quark-mass ensemble, 100 molecular dynamics time units for the other \( a \approx 0.15 \) fm and the 0.12 fm ensembles and 120 time units for the \( a \approx 0.09 \) and 0.06 fm ensembles.

3. Finite-volume and electromagnetic uncertainties

Our treatment of finite-volume effects on the pion and kaon masses and decay constants is the same as described in Ref. [3], and we refer the reader to the discussion there. To summarize very briefly, we adjust these masses and decay constants to their values in a 5.5 fm box, the size of our physical quark-mass lattices, and use these adjusted values in the tuning procedure described above. After the tuning and continuum extrapolation, at which point we have determined \( f_{K^+} \) in a 5.5 fm box, the adjustment is removed to get our result for \( f_{K^+} \) in infinite volume. As an estimate of the remaining finite size uncertainty we use the difference between results using staggered chiral perturbation theory and continuum chiral perturbation theory [next-to-next-to-leading order (NNLO) for \( M_x \) and \( f_{X^+} \), NLO for...
**TABLE VI.** Values for various physical quantities evaluated at zero lattice spacing, as well as statistical and systematic errors, obtained from the simple physical-mass ensemble analysis. Here $\Phi_D^*$ is evaluated at $m_\pi = m_\rho$. The current analysis uses updated inputs for the electromagnetic effects, so we repeat some of the discussion. Because our sea quarks are isospin symmetric, we adjust the experimental inputs to what they would be in a world without electromagnetism or sea-quark isospin violation before matching the simulation data to experiment to find the strange-quark mass $m_s$ and the average light-quark mass $\bar{m} = (m_u + m_d)/2$. Specifically, we do not adjust the neutral pion mass because the leading-order isospin correction to $M_{\pi 0}^2$ is $\propto (m_u - m_d)^2/\Lambda^2_{\chi PT}$ to order isospin correction to $m_\pi$, etc. We also include the effect of subtracting $\pi$ and the ratio $\pi^0$ in $\chi^2_{\chi PT}$.

**FIG. 10** (color online). $F_{p4s}$ and the ratio $F_{p4s}/M_{p4s}$ on each ensemble. Here $f_\pi = 130.41$ MeV was used to set the scale to express $F_{p4s}$ in MeV. The notation and choice of fits is the same as in Fig. 5.

$M_K$ and $f_K$ [3]. This difference, along with other systematic effects, is tabulated in Table VI. Finite size effects on the charm-meson masses and decay constants are, as expected, quite small. Figure 11 shows the charm-meson masses and decay constants on the three ensembles differing only in spatial size, showing no detectable finite size effects.

Our treatment of EM effects also follows Ref. [3], which in turn follows Ref. [2]. The current analysis uses updated inputs for the electromagnetic effects, so we repeat some of the discussion. Because our sea quarks are isospin symmetric, we adjust the experimental inputs to what they would be in a world without electromagnetism or sea-quark isospin violation before matching the simulation data to experiment to find the strange-quark mass $m_s$ and the average light-quark mass $\bar{m} = (m_u + m_d)/2$. Specifically, we do not adjust the neutral pion mass because the leading-order isospin correction to $M_{\pi 0}^2$ is $\propto (m_u - m_d)^2/\Lambda^2_{\chi PT}$.
and therefore small, and the electromagnetic corrections vanish in the chiral limit for neutral mesons and are thus also small. For the kaon, we consider the isospin-averaged mass \( M^2_{K^0} = (M^2_{K^+} + M^2_{K^-})_{\text{QCD}}/2 \), where the subscript “QCD” indicates that the leading EM effects in the masses are removed from the experimental masses [30]. To remove these effects we use results from our ongoing lattice QED + QCD simulations with asqtad sea quarks [34,35] for the parameter \( \epsilon \) that characterizes violations of Dashen’s theorem:

\[
(M^2_{K^0} - M^2_{K^-}) = (1 + \epsilon)(M^2_{\pi^+} - M^2_{\pi^0}),
\]

where the superscript \( \gamma \) denotes the EM contribution to the splittings. In Refs. [34,35], we found \( \epsilon = 0.65(7)(14)(10) \), but this result did not yet adjust for finite-volume effects on the photon field. A recent preliminary result [36] including finite-volume effects is \( \epsilon = 0.84(21) \), and we use that here.

We estimate the uncertainty due to EM effects by varying the values of the EM-subtracted meson masses used in the quark-mass tuning; this affects \( m_u \) the most. We vary the parameter \( \epsilon \) by its error. We also consider possible EM effects on the neutral kaon mass itself, which are less well understood than the EM effects on the \( K^+ - K^0 \) splitting that are described by \( \epsilon \). In Ref. [35], the EM contribution to the squared \( K^0 \) mass was estimated to be about 900 MeV^2. However, this estimate did not take into account the effects of EM quark-mass renormalization, which should be subtracted from the result. A rough calculation of the renormalization effect (using one-loop perturbation theory) suggests it is of order of half the size of the contribution. We thus include as a systematic error the effect of shifting the squared \( K^0 \) mass by 450 MeV^2. We do not consider direct EM effects on the weak matrix elements \( f_{\pi^+} \), \( f_{K^+} \), \( f_{D^+} \), and \( f_{D^0} \), which are by definition pure QCD quantities [30]. Such direct EM effects, however, are relevant in the extraction of CKM elements by comparison with experimental rates, as described in Sec. VI.

The shifts in various quantities resulting from these electromagnetic uncertainties are also tabulated in Table VI. The two effects labeled EM1 and EM2 are combined in quadrature to give our quoted EM systematic errors for \( m_s/m_l \) and \( f_{D^+} \). The EM3 column in Table VI shows the effect of lowering the input \( D_s \) meson mass by 1 MeV, an order-of-magnitude estimate for the electromagnetic effect on this mass, which affects the tuning of the charm-quark mass. This effect has not been directly determined in QCD + QED simulations. Assuming that the EM effect on \( M_{D^+} \) is approximately the same as on \( M_{D_s} \), since the two mesons have the same charge, the EM3 error on the decay constants of these mesons is negligible: To very good approximation, the
changes in $\Phi_{D^{+}}$ and $\Phi_{D_{s}}$ due to the change in the estimate of the charm-quark mass are canceled by the changes in the factors of $M_{D_{s}}^{1/2}$ or $M_{D_{s}}^{1/2}$ in these quantities. The fact that the decay constants themselves are only mildly dependent on the heavy-quark mass (for example, the difference between $f_{D_{s}}$ and $f_{D_{s}}$ is only about 10% [37]) indicates that such cancellations must take place. The EM3 error does lead to a significant uncertainty on $m_{q}/m_{s}$, and we include it in our systematic error estimate for that quantity.

B. Chiral perturbation theory analysis of $f_{D}$ and $f_{D_{s}}$ including unphysical quark-mass ensembles

In this section, we present the combined chiral extrapolation or interpolation and continuum extrapolations used to obtain the physical values of the $D^{+}$ and $D_{s}$ meson decay constants. We first discuss chiral perturbation theory for all-scale follows in Sec. IV B 1, giving the formulas used for the chiral fits and describing our method for incorporating discretization effects into the extrapolation. An explanation of our method for setting the lattice scale follows in Sec. IV B 2. Chiral perturbation theory assumes a mass-independent scale-setting procedure. In practice, we use $F_{p4}$ to set the scale and $F_{p4}/M_{p4}$ to tune the strange sea-quark mass. We take these values from the physical quark-mass analysis in Sec. IV A. This means that the absolute scale comes ultimately from $f_{x^{+}}$, which is used to set the scale in Sec. IV A.

The chiral fits themselves are presented in Sec. IV B 3, while systematic errors in the chiral analysis are described in Sec. IV B 4. Chiral-continuum extrapolation errors are found by considering a large number (18) of alternative chiral fits, as well as six versions of the continuum extrapolation of the inputs, resulting in 108 possibilities. We also estimate finite-volume and EM errors within the chiral analysis by propagating the errors in the corresponding inputs through the chiral fits. Equations (28)–(30) show our results for the charm decay constants from the self-contained chiral analysis with complete systematic error budgets.

1. Chiral perturbation theory for $f_{D^{+}}$ and $f_{D_{s}}$

The quark-mass and lattice-spacing dependence of the decay constant has been derived at one loop in heavy-meson, rooted, all-staggered chiral perturbation theory (HMMeASPT) in Ref. [23]. At fixed heavy-quark mass $m_{Q}$, one may argue following Ref. [38] that inclusion of hyperfine splittings (e.g., $M_{D_{s}}^{1} - M_{D_{s}}^{1}$) and flavor splittings (e.g., $M_{D_{s}}^{2} - M_{D_{s}}^{2}$), but no other $1/m_{Q}$ effects, constitutes a systematic approximation at NLO in HMMeASPT. The argument is based on the power counting introduced by Boyd and Grinstein [39]. With $v$ denoting the light valence quark, $Y$ the $\bar{v}v$ valence meson, and $\Phi_{D_{s}} \equiv f_{D_{s}}/\sqrt{M_{D_{s}}}$, Ref. [23] obtains for the pseudoscalar-taste heavy-light meson:

$$
\Phi_{D_{s}} = \Phi_{0} \left( 1 + \frac{1}{16\pi^{2}f^{2}} \frac{1}{2} \left( - \frac{1}{16} \sum_{S, \Xi} \epsilon(M_{S, \Xi}^{2}) \right) - \frac{3}{3} \sum_{j \in M^{(4)}} \frac{\partial}{\partial M_{Y, V}^{2}} \left[ R^{(3)}_{j} \left( M_{Y}^{(3)}; \mu_{v}^{(3)} \right) J(M_{Y}, \Delta_{s}) \right] \right)
- \left( a^{2} \delta_{v} \sum_{j \in M^{(4)}} \frac{\partial}{\partial M_{Y, V}^{2}} \left[ R^{(3)}_{j} \left( M_{Y}^{(3)}; \mu_{v}^{(3)} \right) J(M_{Y}, \Delta_{s}) \right] \right)
- \left( 3g_{a}^{2} \frac{1}{16} \sum_{S, \Xi} J(M_{S, \Xi}, \Delta_{s} + \delta_{S_{V}}) \right)
- \left( 3g_{a}^{2} \left( a^{2} \delta_{v} \sum_{j \in M^{(4)}} \frac{\partial}{\partial M_{Y, V}^{2}} \left[ R^{(3)}_{j} \left( M_{Y}^{(3)}; \mu_{v}^{(3)} \right) J(M_{Y}, \Delta_{s}) \right] \right) \right)
+ L_{s}(x_{u} + x_{d} + x_{s}) + L_{v}x_{v} + L_{a} \frac{x_{a}}{2},
\right)
$$

where $\Phi_{0}, L_{s}, L_{v},$ and $L_{a}$ are low-energy constants (LECs); the indices $S$ and $\Xi$ run over sea-quark flavors and meson tastes, respectively; $\Delta_{s}$ is the lowest-order hyperfine splitting; $\delta_{S_{V}}$ is the flavor splitting between a heavy-light meson with light quark of flavor $S$ and one of flavor $v$; and $g_{a}$ is the $D^{-}\bar{D}^{+}$ coupling. In infinite volume, the chiral logarithm functions $\ell$ and $J$ are defined by [22,38]

$$
\ell(m^{2}) = m^{2} \ln \frac{m^{2}}{\Lambda^{2}}, \quad \text{[infinite volume]},
$$

$$
J(M, \Delta) = (M^{2} - 2\Delta^{2}) \log(M^{2}/\Lambda^{2}) + 2\Delta^{2} - 4\Delta^{2} F(M/\Delta)
\quad \text{[infinite volume]},
$$

with [40]
CHARMED AND LIGHT PSEUDOSCALAR MESON DECAY ...

\[ F(1/x) = \begin{cases} \frac{-\sqrt{1-x^2}}{x} \left[ \frac{x}{2} - \tan^{-1} \left( \frac{x}{\sqrt{1-x^2}} \right) \right], & \text{if } |x| \leq 1, \\
\frac{-\sqrt{1-x^2}}{x} \ln(x + \sqrt{x^2-1}), & \text{if } |x| \geq 1. \end{cases} \] (11)

The residue functions \( R_{\mu}^{[n,k]} \) are given by

\[ R_{\mu}^{[n,k]}(\{m\}; \{\mu\}) = \frac{\prod_{i=1}^{k} (m_i^2 - m_0^2)}{\prod_{i \neq j} (m_i^2 - m_j^2)}. \] (12)

The sets of masses in the residues are

\[ \mu^{(3)} = \{m_U^2, m_D^2, m_S^2\}, \] (13)
\[ \mathcal{M}^{(3,v)} = \{m_{\bar{\tau}}^2, m_{\bar{\pi}}^2, m_{\bar{\eta}}^2\}, \] (14)
\[ \mathcal{M}^{(4,v)} = \{m_{\bar{\tau}}^2, m_{\bar{\pi}}^2, m_{\bar{\eta}}^2, m_{\bar{\eta}}^2\}. \] (15)

Here taste labels (e.g., \( I \) or \( V \) for the masses) are implicit. We define dimensionless quark masses and a measure of the taste splitting by

\[ x_{u,d,s,v} = \frac{4B}{16\pi^2 f_\pi^2} m_{u,d,s,v} \quad \text{and} \quad x_\Delta = \frac{2}{16\pi^2 f_\pi^2} a^2 \Delta, \] (16)

where \( B \) is the LEC that gives the Goldstone pion mass \( M_{\pi}^2 = B(m_u + m_d) \), and \( a^2 \Delta \) is the mean-squared pion taste splitting. The \( x_j \) are natural variables of HM\( \alpha \)S\( \beta \)PT; the LECs \( L_j \), \( L_v \), and \( L_o \) are therefore expected to be \( \mathcal{O}(1) \). All ensembles in the current analysis have degenerate light sea quarks: \( x_u = x_d = x_l \). The taste splittings have been determined to \( \sim 1\% - 10\% \) precision [7] and are used as input to Eq. (8), as are the taste-breaking hairpin parameters \( \delta_\Lambda \) and \( \delta_\gamma \), whose ranges are taken from chiral fits to light pseudoscalar mesons [41].

To include the finite-volume effects for a spatial volume \( L^3 \) in Eq. (8), we replace [38]

\[ \ell(m^2) \to \ell(m^2) + m^2 \delta_\Lambda(mL) \quad \text{[finite volume]}, \] (17)
\[ J(m, \Delta) \to J(m, \Delta) + \delta J(m, \Delta, L) \quad \text{[finite volume]}, \] (18)

where

\[ \delta J(m, \Delta, L) = \frac{m^2}{3} \delta_\Lambda(mL) - 16a^2 \left[ \frac{2\Delta}{3} J_{\text{FV}}(m, \Delta, L) + \frac{\Delta^2 - m^2}{3} K_{\text{FV}}(m, \Delta, L) \right], \] (19)

with

\[ K_{\text{FV}}(m, \Delta, L) = \frac{\partial}{\partial \Delta} J_{\text{FV}}(m, \Delta, L), \] (20)

and with \( \delta_\Lambda(mL) \) and \( J_{\text{FV}}(m, \Delta, L) \) defined in Refs. [42,43].

Because we have data with \( \sim 1\% \) to less than \( 0.1\% \) statistical errors and 314–366 data points (depending on whether \( a \approx 0.15 \) fm is included), NLO HM\( \alpha \)S\( \beta \)PT is not adequate to describe fully the quark-mass dependence, in particular for masses near \( m_c \). We therefore include all NNLO and NNNLO mass-dependent analytic terms. There are four independent functions of \( x_u, x_l \) and \( x_c \) at NNLO and seven at NNNLO, for a total of 11 additional fit parameters. It is not necessary to keep all the seven terms appearing at NNNLO to get a good fit; nevertheless, we include all of them to make it a systematic approximation at the level of analytic terms.

While Eq. (8) is a systematic NLO approximation for the decay constant at fixed \( m_Q \), we have data on each ensemble with two different values of the valence charm mass: \( m_c^\prime \) and \( 0.9m_c^\prime \), where \( m_c^\prime \) is the value of the charm sea mass of the ensemble, and is itself not precisely equal to the physical charm mass \( m_c \) because of tuning errors, which are in some cases as large as this difference (i.e., \( 10\% \) of \( m_c^\prime \)). Since such changes in the value of the charm mass lead to corrections to decay constants that are comparable in size to those from the pion masses at NLO, Eq. (8) needs to be modified in order to fit the data. We therefore allow the LEC \( \Phi_0 \) to depend on \( m_Q \) as suggested by heavy quark effective theory (HQET). For acceptable fits to the highly correlated data at valence charm masses \( m_c^\prime \) and \( 0.9m_c^\prime \), we need to introduce both \( 1/m_Q \) and \( 1/m_Q^2 \) terms. (For more details see the Appendix.) Furthermore, \( \Phi_0 \) has generic lattice-spacing dependence that must be included to obtain good fits. With HISQ quarks, the leading generic discretization errors are \( \mathcal{O}(a^3a^2) \). But because the high degree of improvement in the HISQ action drastically reduces the coefficient of these leading errors, formally higher \( \mathcal{O}(a^4) \) errors are also apparent, as can be seen from the curvature in Figs. 5–10. In Eq. (8), we thus replace

\[ \Phi_0 \to \Phi_0 \left( 1 + k_1 \frac{\Lambda_{\text{HQET}}}{m_Q} \right) \] (21)

where the \( k_i \) are new physical LECs, \( c_i \) are additional fit parameters, \( \Lambda_{\text{HQET}} \) is a physical scale for HQET effects, and \( \Lambda \) is the scale of discretization effects.

In cases where the valence and sea values of the charm-quark mass differ, \( m_Q \) in Eq. (21) is taken equal to the valence mass. This is based on the expectation from decoupling [44] that effects due to variations in the charm sea mass on low-energy physical quantities are small. Note that HQET tells us that heavy-light decay constants come from the physics of the light quark at scale \( \Lambda_{\text{QCD}} \), despite the presence of the heavy valence quark. Thus we do not introduce extra terms corresponding to the charm sea mass here. As discussed in Sec. IV B 4, however, such terms are
included in alternative fits used to estimate systematic errors.

Generic dependence on $a$ is also allowed for the physical LECs $L_\nu$, $L_\gamma$, $k_1$, and $k_2$. However, because these parameters first appear at NLO in the chiral or HQET expansions, it is sufficient to include at most the leading $a$ dependence, for example:

$$L_\nu \rightarrow L_\nu + L_\nu a S(a \Lambda)^2.$$  \hspace{1cm} (22)

Thus we add four fit parameters related to generic discretization effects: $L_{\alpha \delta}$, $L_{\delta \delta}$, $k_{\alpha \delta}$, and $k_{2 \delta}$. There are also three parameters related to taste-violation effects: $L_{\alpha \omega}$, $\delta'_{k\alpha}$ and $\delta'_{\gamma \omega}$. These parameters are taken proportional to the measured average taste splitting $a^2 \Delta$, which depends on $a$ approximately as $a^2 S(a \Lambda)^2$ [7]. In addition, we find that $m_Q$-dependent discretization errors must be considered if data at the coarsest lattice spacing ($a \approx 0.15$ fm) are included in the fits. This is not surprising because $a m_Q^{\text{phys}} \approx 0.84$ at this lattice spacing, which by the power counting estimates of Ref. [4] suggests $\sim 5\%$ discretization errors (although this may be reduced by dimensionless factors). We therefore add $c_3 a S(am_Q)^2 + c_4 (am_Q)^4$ to the analytic terms in Eq. (8), where $m_Q$ is taken to denote the valence charm mass. If the $a \approx 0.15$ fm data are omitted, good fits may be obtained with $c_3$ and $c_4$ set to zero. As discussed below, one can also add similar terms for the charm sea mass.

For the LEC $g_\pi$, a reasonable range is $g_\pi = 0.53(8)$, which comes from recent lattice calculations [45,46]. When this central value and range are included as Bayesian priors, fits to our full data set tend to pull $g_\pi$ low, several sigma below 0.53. Hence, we simply fix $g_\pi = 0.45$, 1-sigma below its nominal value, in our central fit. This problem is ameliorated for alternative fits, used to estimate the systematic errors, that drop the data at $a \approx 0.15$ fm or that use the experimental value of $f_{K^*}$, rather than that of $f_{K^*}$, for $f$ in Eq. (8). Other alternatives considered in the systematic error estimates are to allow $g_\pi$ to be a free parameter, or to keep it fixed at its nominal value. We give more details about fits with varying treatments of $g_\pi$ in Sec. IV B 4.

### 2. Setting the relative lattice scale

Relative scale setting in the combined chiral analysis is done using $F_{pks}$. The value of $F_{pks}$ in physical units, which is only needed at the end of this analysis, has been obtained by comparison with $f_{K^*}$ in Sec. IV A, as are the other needed inputs: $R_{pks} = F_{pks}/M_{pks}$ and the quark-mass ratios $m_c/m_u$, $m_s/m_u$ and $m_d/m_d$. All those quantities are listed in Table VI, and Fig. 10 shows the data and continuum extrapolations used to determine $F_{pks}$ and $R_{pks}$.

We use $F_{pks}$ in the chiral analysis, rather than $f_{K^*}$ itself, for several reasons. First of all, $F_{pks}$ gives highly precise relative lattice spacings between ensembles. Precision scale setting is required in order to get good chiral fits to our large partially quenched data set (366 points) with large correlations of the points within each ensemble. Second, $F_{pks}$ can be accurately adjusted for mistunings in the sea-quark masses using unphysical-mass ensembles for which the physical valence-quark mass values needed to find $f_{K^*}$ can only be reached by extrapolation. Finally, and perhaps most importantly, there are no logarithms of light pseudoscalar masses ($\sim m_q$) in the S\text{\textsc{pt}} expression for the decay constant $F_{pks}$ [22] evaluated at the relevant quark masses for $F_{pks}$. The lightest meson that enters is a valence-sea meson for quark masses 0.4$m_s$ and $m_s$, which has mass $\sim 325$ MeV (for the Goldstone taste). This means that $F_{pks}$ should be well approximated by its Taylor series in $a^2$, and we do not need to modify Eq. (8) to take into account chiral logarithms that enter through the scale-setting procedure. We have checked this assumption by performing a more complicated three-step analysis: (i) The degenerate light-light decay-constant data for all ensembles are fit to the NLO S\text{\textsc{pt}} form of Ref. [22]. (ii) From the fit, we determine $F_{pks}$, as a function of $a^2$. (iii) The data for $\Phi_{D_s}/F_{pks}^{3/2}$ are fit to Eq. (8) divided by the $3/2$ power of $F_{pks}(a^2)$. The results of this procedure differ from the results reported in Table IX below by less than half of the statistical errors, and the systematic errors are essentially the same in both approaches.

We use a mass-independent scale-setting scheme. We first determine $a F_{pks}$ and $am_{pks}$ on the physical-mass ensembles; then, by definition, all ensembles at the same $\beta$ as a given physical-mass ensemble have a lattice spacing $a$ and value of $am_{pks}$ equal to those of the physical-mass ensemble. Since we do not know the correct strange-quark mass until after the lattice spacing is fixed, $a F_{pks}$ and $am_{pks}$ must be determined self-consistently. We find $am_{pks}$ and $a F_{pks}$ on a given physical-mass ensemble by adjusting $am_{s}$ until $a F(aM) = R_{pks}$. To determine $a F_{pks}$ and $am_{pks}$ accurately, data must be adjusted for mistunings in the sea-quark masses. The sea-quark masses of the physical-mass ensembles are tuned relatively well (especially at 0.09 and 0.06 fm), and adjustments are small. Nevertheless, the adjustments may change the final results of $f_{D^+}$ and $f_{D_s}$ by more than the size of the statistical errors.

To make these adjustments, we first find an approximate value of $am_{pks}$ on each physical-mass ensemble by passing a parabola through $(M/F)^2$ as a function of $m_s$, for the three values of $m_s$ closest to $m_{pks}$. The sea-quark masses are kept fixed (initially, to their values in the run) in this process. We use $(M/F)^2$ here rather than $F/M$, since we expect $M^2$ to be approximately linear in $m_s$, and $F^2$ to be approximately constant. The value of $am_{s}$, where the ratio takes its expected value $1/R_{pks}^2$ is the tentative value of $am_{pks}$, and the corresponding value of $a F$ is the tentative
The adjustment of the data requires a determination of the following derivatives:

$$\begin{align*}
\frac{\partial F^2}{\partial m'_s}, & \quad \frac{\partial F^2}{\partial m'_c}, & \quad \frac{\partial F^2}{\partial m''_c}, & \quad \frac{\partial M^2}{\partial m'_s}, & \quad \frac{\partial M^2}{\partial m'_c}, & \quad \frac{\partial M^2}{\partial m''_c}, \\
\frac{\partial M^2}{\partial m'_s}, & \quad \frac{\partial M^2}{\partial m'_c}, & \quad \frac{\partial M^2}{\partial m''_c}, & \quad \frac{\partial^2 M^2}{\partial m'_s \partial m'_c}, & \quad \frac{\partial^2 M^2}{\partial m'_s \partial m''_c}, & \quad \frac{\partial^2 M^2}{\partial m'_c \partial m''_c}, & \quad (23)
\end{align*}$$

where the derivatives should be evaluated at $m_s = m_{p4s}$, and with $m'_s$, $m'_c$, and $m''_c$ at their physical values. All quantities here are in "$p4s$ units," which are (semi)physical units in which $aF$ and $aM$ have been divided by (the tentative value of) $aF_{p4s}$, and quark masses in lattice units have been divided by (the tentative value of) $am_{p4s}$ (and therefore do not require renormalization). The mixed partial derivatives with $m_s$ are needed because we must adjust the data at different values of $m_s$ in order to iterate the process. Because $M^2$ is approximately linear in $m_s$, the effect of the mixed partials in Eq. (23) is non-negligible, while mixed partials of $F^2$ may be neglected. Since the effects of mistunings are already not much larger than our statistical errors, we expect that we may neglect discretization errors and any mistuning effects in the derivatives themselves. This means that we may use, at all lattice spacings, the values determined for the derivatives in Eq. (23) at any one lattice spacing. This expectation is confirmed by alternative determinations of the derivatives, which give results in agreement with the method we now describe.

Many of the derivatives may be calculated using the 12 ensembles that we have at $a \approx 0.12$ fm. Figure 12 shows the light and strange sea masses of these ensembles. Most of the ensembles have the same charm sea masses, which allows us to determine the derivatives with respect to $m'_s$ and $m'_c$ accurately. We first convert the lattice data to $p4s$ units using (tentative values of) $am_{p4s}$ and $aF_{p4s}$. Ensembles in which the light sea mass is tuned close to $0.1m'_s$, shown inside the dashed blue ellipse in Fig. 12, are then used to determine $\partial F^2/\partial m'_s$, $\partial M^2/\partial m'_s$, and $\partial^2 M^2/\partial m'_s \partial m''_c$. The three derivatives with respect to $m'_s$ are found by fitting a quadratic function to the corresponding quantities of these ensembles, as shown in Fig. 13.

To calculate $\partial F^2/\partial m'_s$, $\partial M^2/\partial m'_s$, and $\partial^2 M^2/\partial m'_s \partial m''_c$, we use the three ensembles with strange sea mass close to its physical value, the ensembles inside the red ellipse in Fig. 12. We fit straight lines to the corresponding data, as shown in Fig. 14. Note that there are small differences in the charm and strange sea masses of these ensembles, but they are taken into account by a small adjustment using the derivatives with respect to $m'_s$ and $m'_c$.

The derivatives with respect to $m'_c$ cannot be calculated directly, because we do not have a group of ensembles with different charm sea masses but equal light and strange sea masses. So we have to determine the charm-mass derivatives indirectly, by investigating ensembles with different charm sea masses after adjusting for their differences in strange and light sea masses. This procedure can be carried out using the three ensembles available at $\approx 0.06$ fm. Since $m'_s$ and $m'_c$ vary by about 10% on these three ensembles, the lever arm is large enough to calculate the derivatives with respect to $m'_c$. We first use the derivatives with respect to $m'_s$ obtained at $\approx 0.12$ fm to adjust the data at $\approx 0.06$ fm for mistuning of the strange sea masses, so only $m'_s$ and $m'_c$ dependence remains. Then we calculate the $m'_c$ derivatives by passing a function linear in both $m'_s$ and $m'_c$ through the three data points for each quantity. The $m'_c$ derivatives thus found feed back into the small adjustments needed at $a \approx 0.12$ fm in order to calculate $m'_c$ derivatives, as discussed in the preceding paragraph. Our estimates of all the needed derivatives are tabulated in Table VII.

It is noteworthy that we can analytically determine the first-order derivatives with respect to $m'_s$ by integrating out the charm quark for processes that occur at energies well below its mass. By decoupling [44], the effect of a heavy
enough) sea quark on low-energy quantities occurs only through the change it produces in the effective value of $\Lambda_{\text{QCD}}$ in the low-energy (three-flavor) theory \cite{47}. (For a pedagogical discussion see Sec. 1.5 of Ref. \cite{48}.) Thus, assuming $m_0^c$ is heavy enough, we may calculate the $m_0^c$ derivatives of any quantity that is proportional to $\Lambda_{\text{QCD}}$, where the proportionality constant is some pure number, independent of the light-quark masses. Examples of such quantities are the LEC $B$ in Eq. (16) and the light-light decay constant in the chiral limit, $f$. At leading order in weak-coupling perturbation theory, one then obtains \cite{48} 

$$\frac{\partial F^2}{\partial m_c} = 2 F \frac{\partial F}{\partial m_c} \approx 4 \frac{F^2}{27 m_c^2} = 0.00504 \ [\text{p4s units}],$$

(25)

$$\frac{\partial M^2}{\partial m_c} \approx 2 m_{\text{p4s}} \frac{\partial B}{\partial m_c} \approx 2 \frac{M^2}{27 m_c^2} = 0.01998 \ [\text{p4s units}],$$

(26)

which agree with our numerical results within 10%; see Table VII. Indeed, the fact that the agreement is this close is probably due to chance, especially for the derivative of the decay constant: Our argument has neglected the difference between $f$ and $F_{\text{p4s}}$, but that difference is $\sim 40\%$.

Having the required derivatives, we now iteratively adjust for mistunings. We first compute $a m_{\text{p4s}}$ and $a F_{\text{p4s}}$, then adjust the data, and repeat the entire process two more times. The values of $a m_{\text{p4s}}$ and $a F_{\text{p4s}}$ have then converged to well within their statistical errors. The results for the lattice spacing $a$ and $a m_s$ are listed in Table VIII. The error estimates of these quantities will be discussed below. Our investigation shows that the errors in the derivatives change $a$ and $a m_s$ by less than their statistical errors, so those errors are not included in the analysis.
discretization effects, only omitted.) Among the introduced fit parameters related to discretization effects, only \( c_1 \) in Eq. (21) and \( k_{1,0} \) in Eq. (22) are taken as free parameters in this fit, and the others are set to zero. This fit gives \( p = 0.033 \), and as illustrated in Fig. 15, the extrapolation of the fit to the coarsest lattice spacing does not follow the corresponding data points. We note that this fit and all other chiral fits in this paper include additional data (not shown) from ensembles at \( a \approx 0.12 \) fm \((\beta = 6.0)\) either with \( m' \) lighter than physical, or with volumes \( 24^3 \times 64 \) and \( 40^3 \times 64 \), which were generated to check finite-volume effects. (See Table 1) Moreover, it is important to realize that the biggest source of variation in the data is not discretization errors, but mistunings of the strange and, most importantly, charm-quark masses.

Adding \( c_2 \delta_S(\alpha m) + c_4(\alpha m)^4 \) to the analytic terms in Eq. (8), as well as including \( c_2 \) in Eq. (21), we get a new fit to the partially quenched data at the three finer lattice spacings. By including these three extra parameters, an excellent fit is achieved, as shown in Fig. 16, and extrapolation of the fit to the coarsest lattice spacing gives lines that pass relatively well through the corresponding data points. This comparison makes clear that higher-order discretization errors are important for the HISQ data, in which the leading-order discretization effects are suppressed.

We have a total of 18 acceptable \((p > 0.1)\) versions of the continuum-chiral fits. Five of the fits drop the \( a \approx 0.15 \) fm ensembles; the rest keep those ensembles. The chiral coupling \( f_\pi \) is generally set to \( f_\pi \), except for two fits with the coupling constant set to \( f_\pi \). The LEC \( g_\pi \) is usually fixed to either its nominal value or to \( 1\sigma \) below its nominal value; however, it is allowed to be a free parameter in four of the fits. The LEC \( B \) in Eq. (16) is generally determined for each lattice spacing separately by fitting all data for the squared meson mass \( M^2 \) vs the sum of the valence masses to a straight line. (At \( a \approx 0.12 \) fm only the ensembles with strange sea masses close to its physical mass are included in the fit.) However, in two versions of the chiral fits, \( B \) is determined from just the data on the physical-mass ensembles at each lattice spacing.

Another difference among the fits is how we determine the strong coupling \( \alpha_s \) in discretization terms such as those with coefficients \( c_2 \) and \( c_3 \). Since the coefficients are free parameters, all that we actually need in the fits is the relative value of \( \alpha_s \) at a given coupling \( \beta \) compared to its value at a fixed, fiducial coupling \( \beta_0 \). In most of the fits, we have used measured light-light pseudoscalar taste splittings to fix this relative value, as in Eq. (6). An alternative, which is used in two of our fits, is to use for \( \alpha_s \) the coupling \( \alpha_V \),

074509-19
determined from the plaquette [33]. The scale for $\alpha_V$ is taken to be $q^*/C_3 = 2.0/a$. Note that the NLO perturbative corrections to $\alpha_V$ have not been calculated for the HISQ action, so we use the result for the asqtad action. Since the $n_f$ dependence of the NLO result is small, we expect the difference to have negligible effects on the results of the fit. This expectation can be tested by, for example, flipping the sign of the $n_f$ term in the asqtad result, which is likely a much bigger change than would actually come from changing from asqtad to HISQ. When we do this, we find that the results change by amounts comparable to or smaller than the statistical errors, and significantly smaller than the total systematic errors. Similar, but usually smaller, changes result from replacing $q^*/C_3 = 2.0/a$, which is another reasonable choice, as discussed in Ref. [7].

We have introduced eight fit parameters related to discretization effects ($c_1$, $c_2$, $c_3$, $L_{\psi}$, $L_{\phi}$, $L_{\delta}$, $k_{1b}$, and $k_{2b}$), but it is not necessary to keep all of them to get an acceptable fit. Dropping some of these parameters, we have different continuum-chiral fits with the number of parameters ranging from 23 to 28. We may also choose to constrain, with priors, the LECs in higher-order (NNLO and NNNLO) analytic terms to be $O(1)$ in natural units [as explained following Eq. (16)]. (Through NLO, where we have the complete chiral expression, including logarithms, we always leave the LECs $\Phi_0$, $L_{\psi}$, $L_{\phi}$, and $L_{\delta}$ completely unconstrained, while $g_{s}$, $\delta_{1}$, and $\delta_{2}$ are constrained by independent analyses as discussed above.) We may similarly constrain the coefficients of discretization terms to be $O(1)$ when the terms are written in terms of a reasonable QCD scale (which we take, conservatively, to be 600 MeV). Among the 18 fits we consider, some have higher-order chiral terms and discretization terms completely unconstrained, and others constrain either the chiral terms, or the discretization terms, or both.

In Eq. (21), $m_Q$ denotes the valence charm mass. To take into account the physical effects of the charm sea masses we can introduce a parameter $k_1'$ to Eq. (21):

$$
\Phi_0 \to \Phi_0 \left(1 + k_1 \frac{\Lambda_{\text{HQET}}}{m_Q} + k_2 \frac{\Lambda_{\text{HQET}}^2}{m_Q^2} + k_1' \frac{\Lambda_{\text{HQET}}}{m_c'} \right) \times (1 + c_1 a \Lambda)^2 + c_2 (a \Lambda)^4),
$$

\[ (27) \]
where $m$ is the mass of the charm mass in the sea. One of our fits adds the parameter $k_0$. Further, discretization errors coming from the charm sea masses can be included by adding $c_0 \Lambda^2 + c_0^4$ to the analytic terms in Eq. (8), and one of the fits makes that addition. It is interesting to note that it is possible to obtain another acceptable fit in which $c_2$ in Eq. (21) is restricted by priors to be much smaller than its value in the central fit, but the $c_0^3$ and $c_0^4$ terms are added. This shows that our lattice data cannot distinguish in detail between various sources of higher-order discretization effects. However, the results in the continuum limit are rather insensitive to these differences.

Since all 18 fits considered have acceptable $p$ values and give correction terms reasonably consistent with expectations from chiral perturbation theory and power counting, whether or not such terms are constrained, we have no strong reason to choose one fit or groups of fits as preferred in comparison to the rest. We therefore choose our “central fit” simply by requiring that it be a fit to all ensembles and that it give results for $\Phi_{D+}$ and $\Phi_{D_s}$ that are as close as possible to the center of the histograms for these quantities from all the fits and from all systematic variations in the inputs (i.e., from the “continuum extrapolation” column in Table VI). This central fit has 27 free parameters, with $g_\pi$ fixed to 1-sigma below its nominal value, and with the $k_1$, $c_3$, and $c_4$ terms discussed in the previous paragraph dropped, but all discretization terms aside from $c_0^3$ and $c_0^4$ kept. In the central fit, $c_2$ in Eq. (21) is equal to 1.3 with $\Lambda = 600$ MeV; while the HQET parameters are $k_1 = -1.0$ and $k_2 = 0.5$, with $\Lambda_{HQET} = 600$ MeV.

Figure 17 shows our central fit to partially quenched data at all four lattice spacings. Extrapolating the parameters to the continuum, adjusting the strange sea-quark mass and charm valence- and sea-quark masses to their physical values, and setting the light sea-quark mass equal to the light valence mass [up to the small difference between $m_d$ and $m_l = (m_u + m_d)/2$] gives the orange band. Putting in the physical light-quark mass then gives the black burst, which is the result for $\Phi_{D+}$. Note that the effect of isospin violation in the valence quarks is included in our result. The effect of isospin violation in the sea has not been included, but we may easily estimate its size by putting in our values for $m_u$ and $m_d$ (instead of the average sea mass $m_l$) in Eq. (8) and in the NNLO and NNNLO analytic terms. This results in a change of only 0.01% in $f_{D^+}$, and a still smaller change in $f_{D_s}$.

The width of the band shows the statistical error coming from the fit, which is only part of the total statistical error, since it does not include the statistical errors in the inputs of the quark masses and the lattice scale. To determine the total statistical error of each output quantity, we divide the
full data set into 100 jackknife resamples. The complete calculation, including the determination of the inputs, is performed on each resample, and the error is computed as usual from the variations over the resamples. (For convenience, we kept the covariance matrix fixed to that from the full data set, rather than recomputing it for each resample.) Each jackknife resample drops approximately ten consecutive stored configurations (50–60 trajectories) from each ensemble with \(\approx 1000\) configurations. This procedure controls for autocorrelations, since all our measures of the autocorrelations of these quantities indicate that they are negligible after four or eight consecutive configurations.

For the physical-mass 0.06 fm ensemble with 583 configurations, we are forced to drop only about six consecutive stored configurations at a time. Our expectation is that the effect of any remaining autocorrelations, while perhaps not completely negligible, is small compared to other sources of error. The total statistical errors computed from the jackknife procedure are only about 10% larger than the statistical error from the chiral-continuum fit, indicating that the inputs are statistically quite well determined. The same procedure is performed to find the total statistical error of \(a\) and \(a_{ms}\) at each lattice spacing.

Figure 18 illustrates how data for \(\Phi_{D^+}\) and \(\Phi_{Ds}\) depend on lattice spacing after adjustment to physical values of the quark masses (blue circles). There is a 2%–3% variation between these points and the continuum value (green square at \(a^2 = 0\)). Note that there is clear curvature in the plot, evidence of significant \(a^4\) terms in addition to the formally leading \(a^2\) terms. Both the small absolute size of the errors, and the competition between formally leading and subleading terms, are typical of highly improved actions such as the HISQ action. The red stars show the contribution from the chiral logarithms (with known taste splittings) to the \(a^2\) dependence of the chiral fit function. The green squares show the corresponding contribution from the analytic fit parameters. The two effects are of comparable magnitudes but the relative sign changes with lattice spacing; both are needed to describe the \(a^2\) dependence of the data.
4. Continuum extrapolation and systematic uncertainties

To determine the systematic error associated with the continuum extrapolation (and chiral interpolation) of the charm decay constants in the chiral perturbation theory analysis, we rerun the analysis with alternative continuum-chiral fits, and with alternative inputs that come from different continuum extrapolations of the physical-mass analysis, listed in the continuum extrapolation column in Table VI.

As mentioned above, we have a total of 18 acceptable versions of the continuum-chiral fits. We also have the six versions of the continuum extrapolations used in the physical-mass analysis that leads to the inputs of quark masses and the lattice scale. This gives a total of 108 versions of the analysis. Histograms of the 108 results for $\Phi_{D^+}$ and $\Phi_{D_s}$ are shown in Fig. 19. Conservatively, we take the maximum difference seen in these results with our central values as the "self-contained" estimate of the continuum extrapolation errors within this chiral analysis. The central fit is chosen to give results that are close to the centers of the histograms, which results in more symmetrical error bars than in the preliminary analysis reported in Ref. [24]. Note that the "acceptable" fits entering the histograms all have $p > 0.1$. If the cutoff is instead taken to be $p > 0.05$, the additional fits allowed would not change the error estimates. However a cutoff of 0.01 or lower would give some additional outliers that would increase the width of the histograms.

As mentioned in Sec. IV B 1, the chiral fits tend to pull $g_\pi$ to low values. We can now look at this effect quantitatively. The central fit, which has $g_\pi$ fixed to 0.45, 1σ below its nominal value of 0.53, has $p = 0.36$ and gives $\Phi_{D^+} = 9191(14)$ MeV$^{3/2}$, where the statistical error comes only from the fit and not from the errors in the inputs. Allowing $g_\pi$ to be a free parameter, with prior range 0.53(8), we find $g_\pi = 0.26(5)$, about 3σ below its nominal value, and $p = 0.71$. However, $\Phi_{D^+}$ then is 9184(15) MeV$^{3/2}$, a change of only half the statistical error, and much less than the systematic error from the range over the results of all chiral-continuum fits. Alternatively, fixing $g_\pi$ to its nominal value gives $\Phi_{D^+} = 9195(13)$ MeV$^{3/2}$, $p = 0.16$. We can also consider the effect in fits that drop the data with $a^2 \approx 0.15$ fm and consequently use fewer lattice-spacing-dependent parameters. When $g_\pi$ is a free parameter with prior range 0.53(8), we find $g_\pi = 0.37(6)$, 2σ below the nominal value, and $\Phi_{D^+} = 9189(12)$ MeV$^{3/2}$, $p = 0.37$. The corresponding fits with $g_\pi$ fixed to its nominal value or one sigma below...
that value give $\Phi_{D^+} = 9196(13)$ MeV$^{3/2}$, $p = 0.18$ and $\Phi_{D^0} = 9192(12)$ MeV$^{3/2}$, $p = 0.30$, respectively. Thus, the systematic error on $\Phi_{D^+}$ associated with the value of $g_\pi$ is small compared to our other errors. The systematic error from $g_\pi$ on $\Phi_{D^+}$ is a factor of 2 smaller still.

The fact that a wide range of $g_\pi$ values give good fits indicates that our data have little to say about the physical value of that parameter. Indeed, even fits with $g_\pi$ set equal to zero have very good $p$ values, and do not change $\Phi_{D^+}$ by more than one statistical $\sigma$. Such a fit that includes all data gives $\Phi_{D^+} = 9180(13)$ MeV$^{3/2}$, $p = 0.83$, and one that drops the data with $a \approx 0.15$ fm gives $\Phi_{D^+} = 9181(13)$ MeV$^{3/2}$, $p = 0.52$.

In practice, the NLO finite-volume corrections are included in our fit function, Eq. (8), when it is applied to the data, and the volume is sent to infinity when the continuum results are extracted. We may conservatively estimate the residual finite-volume error in the heavy-light data either by turning off all finite-volume corrections and repeating the fit, or by using the current fit to find the size of the NLO finite-volume correction on our most-important, 0.06 fm physical-mass ensemble. Yet another way to make the estimate is by direct comparison of our results on the $32^3 \times 64$, $\beta = 6.0$, $m_l/m_s = 0.1$ ensemble (which is similar in physical size to our other $m_l/m_s = 0.1$ ensembles) and the $40^3 \times 64$, $\beta = 6.0$, $m_l/m_s = 0.1$ ensemble. All three methods indicate that there are negligible direct finite-volume effects in the heavy-light lattice data. Nevertheless, there are non-negligible finite-volume effects in our final answers, which appear due to the scale setting in the light-quark sector through, ultimately, $f_{\pi^+}$. (The value of $F_{\rho L}$, in physical units that we use comes by comparison with $f_{\pi^+}$.)

We then propagate the errors in the inputs through our analysis. Electromagnetic errors in the light-quark masses are similarly propagated through our analysis.

Results for $\Phi_{D^+}$, $\Phi_{D^0}$, and their ratio at various values of the mass ratio of light to strange sea quarks are shown in Table IX; only the top subsection of the table gives physical results. Note that the valence masses do not vary in the three different subsections of the table, so changes in results show only the effects of the light sea mass. The EM error associated with the masses of the heavy-light mesons, which we call EM3, is not included in any of the quoted EM errors in the table. As explained in Sec. IV A 3, that is because the error cancels to good approximation when one extracts the decay constants $f_{D^+}/f_D$, from $\Phi_{D^+}/\Phi_{D^0}$. One should use the experimental masses $M_{D^+} = 1869.62$ MeV, $M_D = 1968.50$ MeV [30] in this extraction; the experimental errors in these masses are negligible at the current level of precision.

To quantify the effect of isospin violations, we also report $\Phi_D$ and $\Phi_{D^0} - \Phi_D$, where $\Phi_D$ is the value of $\Phi$ in the isospin limit, when the light valence mass is equal to $m_l = (m_u + m_d)/2$ instead of $m_d$. In this case, the EM errors in the heavy-light meson masses do affect the errors in the corresponding decay constant difference because of the difference between the EM effect in the charged $M_{D^+}$ and in the neutral $M_{D^0}$, which are averaged to obtain $M_D$. We estimate this error when we quote $f_{D^+}/f_D$ below.

In Table X, we report additional results for the case when the light valence mass is kept equal to the light sea mass and $m_l/m_s = 0.1$ or 0.2. These unphysical results may be useful for normalizing other calculations, such as those of $B$-system decay constants, as described in Sec. V.
TABLE IX. Results for \( \Phi \) from the chiral analysis, for three choices of the light sea mass \( m_{\bar{s}} \). \( \Phi_D \) is the value of \( \Phi \) when the light valence mass \( m_v = m_l \equiv (m_u + m_d)/2 \). Valence masses here are always taken to be the physical values \( m_u, m_d \), or \( m_l \), independent of the value of \( m_s \), and the strange sea mass is always physical (\( m_s \equiv m_s \)). In the EM errors on these quantities, we have not included the EM3 error coming from the EM effects on the masses of the corresponding heavy-light mesons. Such errors largely cancel when we compute \( f_{D^+} \) and \( f_{D^0} \) from \( \Phi_{D^+} \) and \( \Phi_{D^0} \), using the experimental meson masses. For \( \Phi_{D^0} \) and \( f_{D^0} \), the situation is more complicated—see text. The negative central value of \( \Phi_{D^0} - \Phi_D \) for \( m'/m_s = 0.2 \) is an effect of partial quenching, but note that the systematic errors are large in this case.

\[
\begin{align*}

\Phi_{D^0} - \Phi_D &= -5.3 \pm 0.3_{-3.3}^{+15.0} \text{ stat } \text{ extrap } + 0.1_{\text{EM}} \pm 0.1_{\text{EM}} \text{ MeV } 3/2 \\
\end{align*}
\]

At each \( \beta \) value, we have reported, in Table VIII, the values for the lattice spacing \( a \) and the strange mass in lattice units \( am_s \), which come from our scale-setting procedure using \( M_{P_L}/F_{P_L} \) and \( aF_{P_L} \). For the estimates of the extrapolation errors in these quantities, we have used the six versions of the continuum extrapolation for the inputs, which are the quark-mass ratios, \( M_{P_L}/F_{P_L} \), and \( F_{P_L} \) in physical units. Finite-volume and electromagnetic errors come simply from propagating the errors in \( f_{D^+} \) and the light-quark masses through the analysis.

The self-contained chiral analysis of the current section gives

\[
\begin{align*}
f_{D^+} &= 212.6 \pm 0.4_{-0.8}^{+0.9} \text{ stat } \text{ extrap } + 0.3_{\text{EM}} \pm 0.0_{\text{EM}} \\
&\pm 0.3_{f_{PDG}} \text{ MeV,} \\
f_{D^0} &= 249.0 \pm 0.3_{-0.9}^{+1.0} \text{ stat } \text{ extrap } + 0.2_{\text{EM}} \pm 0.1_{\text{EM}} \\
&\pm 0.4_{f_{PDG}} \text{ MeV,} \\
f_{D^+}/f_{D^0} &= 1.1712_{-0.0031}^{+0.0034} \text{ stat } \text{ extrap } + 0.0004_{\text{EM}} \pm 0.0005_{\text{EM}} \\
f_{D^0} - f_{D^+} &= 0.47_{-0.0010}^{+0.0014} \text{ stat } \text{ extrap } + 0.0000_{\text{EM}} \pm 0.0000_{\text{EM}} \text{ MeV }
\end{align*}
\]

TABLE X. Results for \( \Phi \) for two choices of light sea masses. Here the valence mass for \( \Phi_D \) is taken equal to the light sea mass: \( m_v = m_l \). The quantities denoted by “phys” are those tabulated in Table IX for the case \( m'/m_s = m_l \).

\[
\begin{align*}
m'/m_s = 0.1 &
\Phi_D &= 9477 \pm 16_{-36}^{+39} \text{ stat } \text{ extrap } + 13_{\text{EM}} \pm 2_{\text{EM}} \text{ MeV } 3/2 \\
\Phi_{D^+} &= 11128 \pm 13_{-36}^{+42} \text{ stat } \text{ extrap } + 12_{\text{EM}} \pm 4_{\text{EM}} \text{ MeV } 3/2 \\
\Phi_{D^+}/\Phi_D &= 1.0338 \pm 0.0005_{-0.0031}^{+0.0009} \text{ stat } \text{ extrap } + 0.0000_{\text{EM}} \pm 0.0001_{\text{EM}} \\
\Phi_{D^0}/\Phi_D &= 1.0311 \pm 0.0004_{-0.0036}^{+0.0010} \text{ stat } \text{ extrap } + 0.0000_{\text{EM}} \pm 0.0002_{\text{EM}} \\
\Phi_{D^+}/\Phi_{D^0} &= 1.0075 \pm 0.0003_{-0.0006}^{+0.0005} \text{ stat } \text{ extrap } + 0.0000_{\text{EM}} \pm 0.0000_{\text{EM}} \\
m'/m_s = 0.2 &
\Phi_D &= 9870 \pm 17_{-36}^{+39} \text{ stat } \text{ extrap } + 13_{\text{EM}} \pm 2_{\text{EM}} \text{ MeV } 3/2 \\
\Phi_{D^+} &= 11250 \pm 15_{-36}^{+44} \text{ stat } \text{ extrap } + 12_{\text{EM}} \pm 4_{\text{EM}} \text{ MeV } 3/2 \\
\Phi_{D^+}/\Phi_D &= 1.0766 \pm 0.0011_{-0.0038}^{+0.0017} \text{ stat } \text{ extrap } + 0.0001_{\text{EM}} \pm 0.0002_{\text{EM}} \\
\Phi_{D^0}/\Phi_D &= 1.0738 \pm 0.0011\text{ stat } \text{ extrap } + 0.0001_{\text{EM}} \pm 0.0002_{\text{EM}} \\
\Phi_{D^+}/\Phi_{D^0} &= 1.0185 \pm 0.0007_{-0.0010}^{+0.0014} \text{ stat } \text{ extrap } + 0.0000_{\text{EM}} \pm 0.0000_{\text{EM}} \\
\end{align*}
\]
where $f_D$ is the decay constant in the isospin limit, $m_u = m_d = m_l$. In finding $f_{D^*} - f_D$ from $\Phi_{D^*} - \Phi_D$ in Table IX, we use the experimental value for $M_{D^*}$ and our result, $M_{D^*} - M_{D^0} = 2.6$ MeV, obtained from the pure-QCD analysis in Sec. IVA. Comparison with the experimental mass difference $M_{D^*} - M_{D^0} = 4.8$ MeV indicates that the EM effect on this difference is $\sim 2.2$ MeV. We take half of this difference, namely 1.1 MeV, as our estimate of the EM effect on the heavy-light masses, and propagate this error to $f_{D^*} - f_D$, adding it in quadrature with other EM errors to get the error quoted in Eq. (31).

V. RESULTS AND CONCLUSIONS

Our main results are for the charm decay constants and their ratio. We take the more precise determinations from the self-contained chiral perturbation theory analysis using the full set of sea-quark ensembles, Eqs. (28)–(30), for our best estimate of the central values and statistical errors. We then use the results of the simpler physical-mass analysis to help estimate the systematic uncertainties. For the continuum extrapolation error, we consider the differences in the central values of $f_{D^*}$, $f_{D_s}$, and $f_{D^*/f_{D^*}}$, obtained with various continuum-extrapolation Ansätze in the physical-mass analysis, and take those differences as the uncertainty whenever they are larger than the error from the chiral analysis. Figure 20 shows the histograms from Fig. 19 overlaid with the results from the various continuum extrapolations considered in Sec. IVA (vertical red lines), as well as our final estimates for the systematic errors of the continuum extrapolation. The analysis on the physical-mass ensembles also gives alternative, and comparably sized, estimates for the finite-volume and EM errors to those in Eqs. (28)–(30) (see Table VI), and we take the larger value as the uncertainty in each case. This procedure yields our final results for $f_{D^*}$, $f_{D_s}$ and $f_{D^*/f_{D^*}}$:

$$f_{D^*} = 212.6 \pm 0.4_{\text{stat}} \pm 0.9_{\text{extrap}} \pm 0.3_{\text{EM}} \text{MeV},$$

$$f_{D_s} = 249.0 \pm 0.3_{\text{stat}} \pm 1.0_{\text{extrap}} \pm 0.2_{\text{EM}} \text{MeV},$$

$$f_{D^*/f_{D^*}} = 1.1712(10)^{\text{stat}}(3)^{\text{extrap}}(6)^{\text{EM}}.$$

For the effects of isospin violation we find

$$f_{D^*/f_{D^*}} = 0.47(1)^{\text{stat}}(28)^{\text{extrap}}(0)^{\text{EM}} \text{MeV},$$

where the continuum-extrapolation error has been increased relative to that in Eq. (31) to take into account the difference from the result of the physical-mass analysis.

We also update our determination of the decay-constant ratio $f_{K^*/f_{\pi^*}}$ in Ref. [3] from the physical-mass analysis using additional configurations on the 0.06 fm physical quark-mass ensemble, and include results for quark-mass ratios coming from the tuning procedure and continuum extrapolation described in Sec. IVA:

$$f_{K^*/f_{\pi^*}} = 1.1956(10)^{\text{stat}}(23)^{\text{extrap}}(5)^{\text{EM}}.$$

$$m_s/m_l = 27.352(51)^{\text{stat}}(80)^{\text{extrap}}(55)^{\text{EM}},$$

$$m_c/m_s = 11.747(19)^{\text{stat}}(52)^{\text{extrap}}(28)^{\text{EM}}.$$

FIG. 20 (color online). The same as Fig. 19, but the histograms of $\Phi_{D^*}$ and $\Phi_{D_s}$ from the chiral analysis have been overlaid with results from various continuum extrapolations in the physical-mass analysis, shown as vertical red lines. We take the full ranges shown at the top of each plot as the final estimates of the systematic errors coming from the continuum extrapolation.
Although our analysis also determines \( m_u/m_d \), we do not quote a final result, because the errors in this ratio are dominated by electromagnetic effects. If we take the results from our preliminary study of EM effects on pion and kaon masses reported in Ref. [36] at face value, we obtain a central value for \( m_u/m_d = 0.4482(48)_{\text{stat}}^{+21}_{-11.5} \mu^2_{\text{extrap}}(1)_{\text{PV}} \), where we include the uncertainties from all sources other than EM. Once the full analysis of \( m_u/m_d \) from our QCD + QED simulations is complete, we expect the EM error to lie between 0.0150 and 0.0230. Even the more conservative estimate for the EM error on \( m_u/m_d \), however, would not impact the uncertainties on our final results in Eqs. (32)–(38) significantly; the electromagnetic error is subdominant for most of these quantities, and one of several comparable sized errors in the case of \( m_u/m_l \). With the charm-quark mass tuned to match the \( D_s \) mass, our analysis gives a mass for the \( \eta_c \) of 2982.33(0.35)(+2.34)(-2.07) MeV. While this mass is in good agreement with the experimental value, it should be remembered that our calculation does not include the effects of disconnected contractions or decay channels to the \( \eta_c \) mass. Finally, we note that we are computing the values of the decay constants as they are conventionally defined, in a pure-QCD world. Comparison to experiment thus requires a matching of the decay rates between QCD and QCD + QED. The errors in such a matching are not included in our error budgets for the decay constants but are accounted for in our determinations of CKM matrix elements in Sec. VI.

Figures 21–24 compare our results for \( m_u/m_l, m_c/m_s, f_{K^+}/f_{\pi^+} \) and the charm decay constants with other unquenched calculations. Our results agree with most determinations at the 1–2\( \sigma \) level. In particular, our value for \( f_{D_s} \) agrees with the second-most-precise determination from HPQCD obtained using HISQ valence quarks on the (2 + 1)-flavor MILC asqtad ensembles [49]. We disagree slightly with HPQCD’s determination of the ratio \( f_{D_s}/f_{D^*} \) [50], but only by 1.2\( \sigma \). Our result for \( f_{D_s} \) is more precise than previous determinations primarily for two reasons. First, the statistical errors in our data points for the decay amplitudes are 2 or more times smaller than those obtained by, for example, HPQCD [49]. Second, our use of ensembles with the physical light-quark mass eliminates the significant (although not dominant) uncertainty from the chiral extrapolation. For \( f_{D^*} \) and \( f_{D_s}/f_{D^*} \), we also have significantly smaller continuum-extrapolation errors due to the use of the HISQ sea-quark action and lattice spacings down to \( a \approx 0.06 \) fm.

The dominant source of uncertainty in our results is from the continuum extrapolation and will be reduced once we include a still finer ensemble in our analysis with \( a \approx 0.045 \) fm and \( m_l/m_s = 0.2 \), generation of which is in progress. In fact, we already have some preliminary data on this ensemble, albeit with small statistics, and have tried including these data in the current chiral fits. The fits have acceptable \( p \) values and give results that are less than one statistical sigma away from those in Eqs. (32)–(36). Once we have ensembles with lattice spacings as fine as \( a \approx 0.03 \) fm, we expect to be able to use the same methods employed here to compute bottom decay constants. In the meantime, however, our results for \( D \)-meson decay constants using HISQ charm quarks can be combined with calculations of the ratios \( \Phi_B/\Phi_{D_s} \) using Fermilab heavy quarks to improve the determinations of decay constants in the \( B \) system, where the use of the HISQ action is more difficult. The ratios of continuum-extrapolated decay constants at various unphysical values of the light-quark mass may also be useful for this approach. The analysis of \( B \)- and \( D \)-meson decay constants with Fermilab heavy quarks on the 2 + 1 flavor asqtad ensembles is presently being finalized [77].

**FIG. 21** (color online). Unquenched lattice results for \( m_f/m_l \) [25,51–56] and \( m_c/m_s \) [51,57–59]. Results are grouped by the number of flavors from top to bottom: \( n_f = 2 \) (green diamonds), \( n_f = 2 + 1 \) (blue circles), and \( n_f = 2 + 1 + 1 \) (purple squares). Within each grouping, the results are in chronological order. Our new results are denoted by magenta crosses and displayed at the bottom of each plot.
we have estimated the difference in Eq. (35). Again, we do not distinguish results in the isospin symmetric limit (degenerate up and down quarks) and results including isospin violation. The difference is small [37] and does not affect the qualitative picture. (Our result does include the up-down quark mass difference, and so is for $f_K/f_{\pi}$.)

![FIG. 22 (color online). Unquenched lattice results for $f_K/f_{\pi}$ [25,52–56,60–68]. The previous results are reviewed in [37]. Results are grouped by the number of flavors from top to bottom: $n_f = 2$ (green diamonds), $n_f = 2 + 1$ (blue circles), and $n_f = 2 + 1 + 1$ (purple squares). Within each grouping, the results are in chronological order. Our new result is denoted by a magenta cross and displayed at the bottom. In this plot we do not distinguish between results done in the isospin symmetric limit (degenerate up and down quarks) and results including isospin violation. The difference is small [37] and does not affect the qualitative picture. (Our result does include the up-down quark mass difference, and so is for $f_K/f_{\pi}$.)](image1)

We now use our decay constant results to obtain values for CKM matrix elements within the Standard Model and to test the unitarity of the first and second rows of the CKM matrix.

The decay-constant ratio $f_{K^+}/f_{\pi^0}$ can be combined with experimental measurements of the corresponding leptonic decay widths to obtain a precise value for the ratio $|V_{us}|/|V_{ud}|$ [1]. Combining our updated result for $f_{K^+}/f_{\pi^0}$ from Eq. (36) with recent experimental results for the leptonic branching fractions [30] and an estimate of the hadronic structure-dependent EM correction [78], we obtain

$$|V_{us}|/|V_{ud}| = 0.23081(52)_{\text{LQCD}}(29)_{\text{BR(K)}}(21)_{\text{EM}}.$$ (39)

Taking $|V_{ud}|$ from nuclear $\beta$ decay [79], we also obtain

$$|V_{us}| = 0.22487(51)_{\text{LQCD}}(29)_{\text{BR(k)}}(20)_{\text{EM}}(5)_{\text{V_{ud}}}.$$ (40)

This result for $|V_{us}|$ is more precise than our recent determination from a calculation of the kaon semileptonic form factor on the physical-mass HISQ ensembles [80], and larger by 1.8. Figure 25 shows the unitarity test of the first row of the CKM matrix using our result for $f_{K^+}/f_{\pi^0}$.

We find good agreement with CKM unitarity and obtain a value for the sum of squares of elements of the first row of the CKM matrix consistent with the Standard-Model prediction zero at the level of $10^{-3}$:

$$1 - |V_{ud}|^2 - |V_{us}|^2 - |V_{ub}|^2 = 0.00026(51).$$ (41)
contributions that depend on the hadronic structure, lead to uncertainties in these corrections, in particular from the fD and kaon leptonic decay constants to be estimated therein). Such contributions are estimated for pion semileptonic form factor at q^2 = 0 [80]. The diagonal black line is the unitary prediction and lies well within the region of overlap of the magenta and orange bands. Right: Squared magnitudes of elements of the second row of the CKM matrix. The green vertical and blue horizontal bands show the region of overlap of the two colored bands, indicating a slight tension with CKM unitarity.

Thus our result places stringent constraints on new-physics scenarios that would lead to deviations from first-row CKM unitarity. Finally, we note that, now that the uncertainty in |V_{us}|^2 is approximately the same as that in |V_{ud}|^2, it is especially important to scrutinize the current uncertainty estimate for |V_{ud}|.

The D^+ and D_s-meson decay constants can be combined with experimental measurements of the corresponding leptonic decay widths to obtain |V_{cd}| and |V_{cs}|. The values f_{D^+}|V_{cd}| = 46.06(1.11) MeV and f_{D_s}|V_{cs}| = 250.66(4.48) MeV in the PDG [81] are obtained from averaging the experimentally measured decay rates into electron and muon final states including an estimate of structure-dependent Bremsstrahlung effects that lowers the D^+ → μ^+ ν_μ rate by ~1% [82,83]. The PDG determinations of f_{D^+}|V_{cd}| and f_{D_s}|V_{cs}| do not, however, take into account other electroweak corrections (cf. Refs. [1,84], and references therein). Such contributions are estimated for pion and kaon leptonic decay constants to be ~1%–2%, and the uncertainties in these corrections, in particular from the contributions that depend on the hadronic structure, lead to ~0.1% uncertainties in |V_{us}|/|V_{ud}| and |V_{us}| obtained from leptonic decays. Now that the uncertainties in the charm decay constants are at the half-a-percent level, it is timely to consider including electroweak corrections when extracting |V_{cd}| and |V_{cs}| from leptonic D decays, and we attempt to provide a rough estimate of their possible size here. We consider all of the contributions that have been estimated for pion and kaon leptonic decays. Not all of the necessary calculations have been performed for the charm system, however, so, where necessary, we use results for the pion and kaon system as a guide and take a generous uncertainty.

The universal long-distance EM contribution to leptonic decays of pointlike charged particles was calculated by Kinoshita [85]. Evaluating this contribution for leptonic D decays into muons (because the experimental averages are dominated by measurements in the muon channel), the long-distance correction lowers both the D^+ and D_s decay rates by about 2.5%. The universal short-distance contribution to leptonic decays of charged pseudoscalar mesons, which accounts for electroweak corrections not included in the definition of G_F, was computed by Sirlin [86]. Choosing M_D for the factorization scale that enters ln(M_D/μ), the “Sirlin factor” increases the D^+ and D_s leptonic decay rates by about 1.8%. Thus the net effect of these two known corrections is a slight decrease in the D^+ and D_s rates by less than a percent. Finally, we consider EM effects that depend on the mesons’ hadronic structure. The expressions for the structure-dependent contributions to charged pion and kaon decay rates have been computed at O(e^2 p^2) and O(e^2 p^4) in chiral perturbation theory [87,88]. The dominant O(e^2 p^2) contribution takes the form c_1^{(p)} α/π, and the coefficients have been estimated numerically in the large-N_c approximation to be c_1^{(p)} = -2.4(5)
and $c_1^{(K)} = -1.9(5)$ [89]. These calculations do not apply to the charm system, however, because the $D_{s}\pi$ meson masses are much heavier than the pion and kaon masses, and well outside the range of validity of the light-meson chiral expansion. We therefore consider the possibility that the analogous coefficients for the $D$ system are 2–5 times larger than for the pion and kaon system. With this assumption, we find a range of the possible size for the hadronic correction to the $D^+ \rightarrow D^- \pi^+$ and $D_s^- \rightarrow D^- \pi^-$ leptonic decay rates from 1.1% to 2.8%. Corrections of this size would not be negligible compared to the known short-distance and long-distance contributions; thus it is important to obtain a more reliable estimate of the contributions to charged $D$ decays due to hadronic structure in the future.

For the determinations of $|V_{cd}|$ and $|V_{cs}|$ given here, we first adjust the experimental decay rates quoted in the PDG by the known long-distance and short-distance electroweak corrections. We then add an estimate of the uncertainty due to the unknown hadronic structure-dependent EM corrections, taking the lower estimate of 0.6%. With these assumptions, and using our results for $f_{D^+}$ and $f_{D_s}$ from Eqs. (32) and (33), we obtain

$$|V_{cd}| = 0.217(1)_{\text{LOQCD}}(5)_{\text{exp}}(1)_{\text{EM}}.$$  \hspace{1cm} (42)

$$|V_{cs}| = 1.010(5)_{\text{LOQCD}}(18)_{\text{exp}}(6)_{\text{EM}}.$$  \hspace{1cm} (43)

where “EM” denotes the error due to unknown structure-dependent EM corrections. In both cases, the uncertainty is dominated by the experimental error in the branching fractions. Thus the significant improvement in $f_{D^+}$ and $f_{D_s}$ does not, at present, lead to direct improvement in $|V_{cd}|$ and $|V_{cs}|$. Experimental measurements of the $D^+$ decay rates have improved recently [81]; however, such that the error on $|V_{cd}|$ from leptonic $D^+$ decays is now approximately half that of $|V_{cd}|$ obtained from either neutrinos [30] or semileptonic $D \rightarrow \pi \nu \bar{v}$ decay [90].

Our result for $|V_{cd}|$ agrees with the determination from neutrinos. Our $|V_{cd}|$ is 1.0σ lower than the determination from semileptonic $D$ decay in Ref. [90], while our $|V_{cs}|$ is 1.1σ higher than that of Ref. [91]. Figure 25 shows the unitarity test of the second row of the CKM matrix using our results for $f_{D^+}$ and $f_{D_s}$. We obtain a value for the sum of squares of elements of the second row of the CKM matrix of

$$1 - |V_{cd}|^2 - |V_{cs}|^2 - |V_{cb}|^2 = -0.07(4).$$  \hspace{1cm} (44)

showing some tension with CKM unitarity. This test will continue to become more stringent as experimental measurements of the $\bar{D}^+$ and $D_s$ decay rates become more precise. At present, even if our rough estimate of the uncertainty due to structure-dependent EM corrections in Eqs. (42) and (43) is too small by a factor of 2, the errors on $|V_{cd}|$ and $|V_{cs}|$ would not change significantly. It will be important, however, to obtain a more reliable estimate of the contributions to charged $D$ decays due to hadronic structure in the future.

APPENDIX: EXPANSION OF $\Phi_0$ IN TERMS OF $1/m_Q$

Equation (8) contains the effects of hyperfine splittings (e.g., $M_D - M_{\bar{D}}$) and flavor splittings (e.g., $M_{D_s} - M_D$), but no other $1/m_Q$ effects. Boyd and Grinstein [39] find

074509-30
some other contributions at the same order as hyperfine and flavor splittings. However, one can show that most of these terms only produce $1/m_Q$ corrections to the LECs relevant to the pseudoscalar-meson decay constants. (Some of the terms violate heavy-quark spin symmetry and therefore give different contributions to the pseudoscalar and vector-meson decay constants at this order, but we are not concerned with vector-meson decay constants here.) Following Eq. (20) of Ref. [39], at the order of $O(1/m_Q, m_0)$, where $m_0$ is a light-quark mass, the $1/m_Q$ terms can be included by replacing $\Phi_0$ by $\Phi_0(1 + \text{const}/m_Q)$. This dependence can be simply absorbed in $\Phi_0$ for a fixed value of $m_Q$. However, in our analysis the charm mass varies by about 10%, which leads to a correction comparable to that produced by terms of $O(m_0) \sim O(m_\pi^2)$. Therefore, replacing $\Phi_0$ by $\Phi_0(1 + \text{const}/m_Q)$ in Eq. (8) should be considered a NLO correction. At this order the rate for $D^* \rightarrow D\pi$ is governed by $g_\pi (1 + \text{const}/m_Q)$ instead of $g_\pi$, which is already taken into account by incorporating the range $g_\pi = 0.53(8)$ in the fits. We do not allow any further dependence of $g_\pi$ on $m_Q$ in our analysis, because this dependence is formally NNLO.

On each ensemble, we have data with two different values of the valence charm mass: $m_c'$ and $0.9m_c'$, where $m_c'$ is the charm sea mass of the ensemble. In Fig. 26, the ratio of $\Phi_D$ at $m_c'$ to $\Phi_D$ at $0.9m_c'$ is shown in terms of $m_\pi$ for our four lattice spacings. The fact that $\Phi_D(m_c')/\Phi_D(0.9m_c')$ does not vary much as a function of the light valence-quark mass is evidence that the $1/m_Q$ effects can be absorbed in the overall factor in front of the full one-loop result as discussed above. On the other hand, $\Phi_D$ computed at $m_c'$ and at $0.9m_c'$ are highly correlated so that their ratio is known precisely. Since our fits take the correlations into account, the $p$ values will be low unless the chiral form is able to reproduce the ratio to high accuracy. Therefore, the expansion of the overall factor, $\Phi_0$, in terms of $1/m_Q$ needs to be taken beyond the first order; for acceptable fits we need to introduce a $1/m_2Q$ term as well as the $1/m_Q$ term, as indicated in Eq. (21). Furthermore, good fits require the LEC $k_1$ in Eq. (21) to have generic dependence on $a$; such dependence for $k_2$ is also strongly preferred by the fits.

Note finally that Fig. 26 shows a roughly 4% difference between $\Phi_D$ at $m_c'$ and at $0.9m_c'$. As claimed in the discussion above Eq. (21), this is comparable to the chiral NLO effects of a nonzero pion mass, which may be estimated from the fits shown in Fig. 17. Indeed, those fits imply that the difference between the physical value of $\Phi_D$ and its value in the (two-flavor) chiral limit is roughly 3%.

![Figure 26](color online) The ratio $\Phi_D(m_c')/\Phi_D(0.9m_c')$ (where $m_c'$ is the charm sea mass of the ensembles) as a function of $m_\pi$, the light valence-quark mass. The upper left panel shows data at $a \approx 0.15$ fm. The upper right panel shows the data at $a \approx 0.12$ fm from the ensembles with $m_t$ tuned close to its physical value. In the second row, we show $a \approx 0.09$ fm (left) and $a \approx 0.06$ fm (right) data.
